ELEVENTH EDITION
REVISED, ENLARGED, AND ENTIRELY RESET

# PREFACE TO ELEVENTH EDITION

Perhaps the most important change in the present edition of this book, is the omission of matter pertaining strictly to ore mining, in order that the space formerly occupied by it, and a large amount in addition, might be devoted to coal mining. In consequence of this, the publishers have deemed it wise to change the title from "The Coal and Metal Miners' Pocketbook," to "The Coal Miners' Pocketbook." It is believed that the pocketbook will still prove of interest and value to all men engaged in mining, as well as to many in other branches of engineering, but it seemed no longer possible, within the limits of a compact handbook, to cover both fields in full detail.

The present edition represents a thorough revision. Not only have material changes been made throughout the text, but substantial additions to many sections, which bring the work up to date, and, it is hoped, increase its usefulness.

The subjects of Weights and Measures and Mathematics have been entirely rewritten and greatly enlarged. The department on Surveying has been expanded to include Leveling with the aneroid barometer, so much of Railroad Surveying as is necessary at mines, and Determination of the Meridian, both by solar and pole-star observations; and to it have been added some practical notes on Surveying, as ordinarily practised in flat seams. Under the heading of Mechanics, Strength of Materials, etc., will be found very complete tables of specific gravities and weights of various substances per cubic foot. The department on Concrete Construction is entirely new and complete and is of timely interest. Hydrostatics and Hydraulics have been enlarged by the addition of entirely new tables. Pump Machinery now includes centrifugal pumps. The department on Fuels has been practically rewritten and now contains the best formulas for calculating the heating values of coals from their proximate and ultimate analyses, as well as very complete tables of analyses of American and foreign coals. The notes upon Prospecting include the newer types of drilling machinery. The matter on Mine Timbering is practically new and includes notes on the preservation of timber, steel timbers, etc. The subject of Flushing Culm has been brought up to date with numerous examples drawn from recent practice. The subjects of Explosives and Mining Machines have been rewritten on the lines of modern practice. Under Hoisting and Haulage will be found much entirely new matter on gasoline and storage-battery motors, and the subject of Tracklaying has been entirely rewritten. The subject of the Treatment of Injured Persons is now up to date, and the Glossary has been enlarged.

Those who use this book are kindly and earnestly requested to advise us of any errors or omissions they may note and to offer suggestions for the betterment of subsequent editions.

## WEIGHTS AND MEASURES

### LINEAR MEASURE

Immediately following each table of weights or of measures is given a table of equivalents showing the relation existing between the different denominations. All figures on the same horizontal line are of equal or equivalent value.

The United States unit of length, of which unit all other denominations are multiples or submultiples, is the *yard*, originally derived from the Imperial yard of Great Britain. Since 1893, the United States Bureau of Standards has been authorized to derive the yard from the meter, using the relationship established by Congress in the act of July 28, 1866, viz., 1 yard $= \frac{3,600}{3,937}$ meter.

| | |
|---|---|
| 12 inches (in.)........ | = 1 foot........ ft. |
| 3 feet.............. | = 1 yard........ yd. |
| 5.5 yards.......... | = 1 rod........ rd. |
| 40 rods........... | = 1 furlong..... fur. |
| 8 furlongs....... | = 1 mile........ mi. |

| in. | ft. | yd. | rd. | fur. | mi. |
|---|---|---|---|---|---|
| 1 = .083333 | = .027778 | = .005051 | = .000126 | = .000016 | |
| 12 = | 1 = .333333 | = .060606 | = .001515 | = .000189 | |
| 36 = | 3 = | 1 = .181818 | = .004545 | = .000568 | |
| 198 = | 16.5 = | 5.5 = | 1 = .025000 | = .003125 | |
| 7,920 = | 660 = | 220 = | 40 = | 1 = .125000 | |
| 63,360 = | 5,280 = | 1,760 = | 320 = | 8 = | 1 |

The rod of 16.5 ft., and variously known as the *perch* or *pole*, is the same as in surveyor's measure. The furlong is now no longer used.

The *land league* of 3 statute mi. is 15,840 ft.; the *nautical*, or *marine*, *league* of 3 geographical mi. is 18,240 ft.

The nautical, marine, or geographical mile is the $\frac{1}{60}$ part of 1° of a great circle of a sphere whose surface is equal to the surface of the earth. This is commonly taken as 6,080 ft., but is more accurately 6,080.26 ft., and is equivalent to 1.1516 stat. mi. One statute mile equals .8684 naut. mi.

The *fathom* of 6 ft. is used at sea in measuring depths of water, and some times (England) in giving depths of mine shafts.

The *pace* is commonly 3 ft. The U. S. military pace is 30 in.

### SURVEYOR'S LINEAR MEASURE

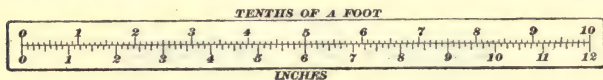
The surveyor's linear measure is no longer in common use but its denominations are found in descriptions of the boundaries of farms taken from old deeds. Lengths of land lines are now measured and recorded in feet and decimal parts thereof.

| | |
|---|---|
| 7.92 inches (in.)...... | = 1 link.............li. |
| 25 links........... | = 1 rod (16.5 ft.).....rd. |
| 4 rods........... | = 1 chain (66 ft.).....ch. |
| 80 chains.......... | = 1 mile.............mi. |

| in. | li. | rd. | ch. | mi. |
|---|---|---|---|---|
| 1 = | .126263 = | .005051 = | .001263 = | .000016 |
| 7.92 = | 1 = | .040000 = | .010000 = | .000125 |
| 198 = | 25 = | 1 = | .250000 = | .003125 |
| 792 = | 100 = | 4 = | 1 = | .012500 |
| 63,360 = | 8,000 = | 320 = | 80 = | 1 |

Surveyors commonly use the engineer's chain of 50 or 100 ft., the feet being divided into tenths and hundredths.

The annexed scale shows on one side, proportionately reduced, a scale of tenths. On the other, a scale of twelfths, corresponding to inches. To reduce inches to decimal parts of a foot, find the number of inches and fractional parts thereof on the side marked "inches." Opposite, on the scale of

TENTHS OF A FOOT / INCHES


tenths, will be found the decimal part of a foot. Thus, if it is wanted to find the decimal part of a foot represented by 7½ in., find the mark corresponding to 7½ in. on the side marked "inches." Opposite this mark may be read 6 tenths, 2 hundredths, and 5 thousandths; or, expressed decimally, .625. This scale may be laid out, full size, upon stiff cardboard and will be found very useful in figuring lengths in construction work.

## DECIMALS OF AN INCH AND MILLIMETERS FOR EACH 1-64TH IN.

| 64ths of an Inch | Decimal Parts of 1 In. | Millimeters | 64ths of an Inch | Decimal Parts of 1 In. | Millimeters |
|---|---|---|---|---|---|
| 1/64 | .015625 | .397 | 33/64 | .515625 | 13.097 |
| 1/32 | .031250 | .794 | 17/32 | .531250 | 13.494 |
| 3/64 | .046875 | 1.191 | 35/64 | .546875 | 13.891 |
| 1/16 | .062500 | 1.588 | 9/16 | .562500 | 14.288 |
| 5/64 | .078125 | 1.984 | 37/64 | .578125 | 14.684 |
| 3/32 | .093750 | 2.381 | 19/32 | .593750 | 15.081 |
| 7/64 | .109375 | 2.778 | 39/64 | .609375 | 15.478 |
| 1/8 | .125000 | 3.175 | 5/8 | .625000 | 15.875 |
| 9/64 | .140625 | 3.572 | 41/64 | .640625 | 16.272 |

## MEASURES OF SURFACE

### SQUARE MEASURE

| 144 square inches (sq. in.) | = 1 square foot | sq. ft. |
| 9 square feet | = 1 square yard | sq. yd. |
| 30.25 square yards | = 1 square rod | sq. rd. |
| 40 square rods | = 1 rood | rood. |
| 4 roods (160 sq. rd.) | = 1 acre | A. or ac. |
| 640 acres = 1 section | = 1 square mile | sq. mi. |

| sq. in. | sq. ft. | sq. yd. | sq. rd. | rood | A. | sq. mi. |
|---|---|---|---|---|---|---|
| 1 = | .006944 = | .000772 = | .000026 | | | |
| 144 = | 1 = | .111111 = | .003673 = | .000092 = | .000023 | |
| 1,296 = | 9 = | 1 = | .033058 = | .000826 = | .000207 | |
| 39,204 = | 272.25 = | 30.25 = | 1 = | .025000 = | .006250 = | .000009 |
| 1,568,160 = | 10,890 = | 1,210 = | 40 = | 1 = | .250000 = | .000391 |
| 6,272,640 = | 43,560 = | 4,840 = | 160 = | 4 = | 1 = | .001563 |
| 4,014,489,600 = | 27,878,400 = | 3,097,600 = | 102,400 = | 2,560 = | 640 = | 1 |

The square rod is also known as the *perch.* The rood, equal to 40 sq. rd., or ¼ A., is obsolete. 640 A. make one section; 320 A., one half-section; 160 A., a quarter section, etc. 36 sections, or 23,040 A., make 1 township (twp.). The areas of small tracts of land, such as city lots, are usually given in square feet and decimals thereof; of larger bodies of land, in acres and decimals of an acre. A square measuring 208.71 ft., or 69.57 yd., on each side contains 1 A.

*Squares* of 100 sq. ft. or of 1 sq. yd. are used in estimating various kinds of work, such as roofing, lathing, plastering, etc. It is advisable to specify the size of the square in all contracts.

### SURVEYOR'S SQUARE MEASURE

The surveyor's square measure is practically obsolete in the United States, although its denominations are commonly found in old deeds in describing the area of lands. As lengths of land lines are now generally measured in feet, tenths, and hundredths, areas are commonly expressed in square feet or in acres and in decimal parts thereof.

| 62.7264 square inches (sq. in.) | = 1 square link | sq. li. |
| 625 square links | = 1 square rod | sq. rd. |
| 16 square rods | = 1 square chain | sq. ch. |
| 10 square chains | = 1 acre | A. or ac. |
| 640 acres = 1 section | = 1 square mile | sq. mi. |
| 36 square miles | = 1 township | tp. or twp. |

| sq. in. | sq. li. | sq. rd. | sq. ch. | A. | sq. mi. |
|---|---|---|---|---|---|
| 1 = | .015942 = | .000026 = | .000002 | | |
| 62.7264 = | 1 = | .001600 = | .000100 = | .000010 | |
| 39,204 = | 625 = | 1 = | .062500 = | .006250 = | .000009 |
| 627,264 = | 10,000 = | 16 = | 1 = | .100000 = | .000156 |
| 6,272,640 = | 100,000 = | 160 = | 10 = | 1 = | .001563 |
| 4,014,489,600 = | 64,000,000 = | 102,400 = | 6,400 = | 640 = | 1 |

1 *township* = 36 sq. mi. = 23,040 A. = 230,400 sq. ch. = 3,686,400 sq. rd. = 2,304,000,000 sq. li. = 144,521,625,600 sq. in.

## MEASURES OF WEIGHT

The United States standard of weight is the troy pound of Great Britain from which the avoirdupois pound is derived in the ratio 1 pound avoirdupois = $\frac{7,000}{5,760}$ pound troy. Since 1893, the United States Bureau of Standards has been authorized to derive the pound avoirdupois from the kilogram, using the

relationship established by Congress in the act of July 28, 1866, viz., 1 pound avoirdupois $= \frac{1}{2.2046}$ kilogram. The weight of the grain in the troy, apothecaries', and avoirdupois pounds, is the same.

### TROY WEIGHT

Troy weight is used in weighing gold and silver.

| | | |
|---|---|---|
| 24 grains (gr.)........ | = 1 pennyweight..... | dwt. |
| 20 pennyweights..... | = 1 ounce.......... | oz. |
| 12 ounces.......... | = 1 pound.......... | lb. |

| gr. | dwt. | oz. | lb. |
|---|---|---|---|
| 1 = | .041667 = | .002083 = | .000174 |
| 24 = | 1 = | .050000 = | .004167 |
| 480 = | 20 = | 1 = | .083333 |
| 5,760 = | 240 = | 12 = | 1 |

1 oz. troy = 1 oz. apothecaries' = 1.09714 oz. avoirdupois
1 lb. troy = 1 lb. apothecaries' = .82286 lb. avoirdupois
1 oz. avoirdupois = .91146 oz. troy or apothecaries'
1 lb. avoirdupois = 1.21528 lb. troy or apothecaries'

### APOTHECARIES' WEIGHT

| | | |
|---|---|---|
| 20 grains (gr.)..... | = 1 scruple..... | sc. |
| 3 scruples........ | = 1 dram....... | dr. |
| 8 drams.......... | = 1 ounce...... | oz. |
| 12 ounces........ | = 1 pound...... | lb. |

### DECIMALS OF A FOOT FOR EACH 1-64TH IN.

| Inch | 0″ | 1″ | 2″ | 3″ | 4″ | 5″ | 6″ | 7″ | 8″ | 9″ | 10″ | 11″ |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 0 | 0 | .0833 | .1667 | .2500 | .3333 | .4167 | .5000 | .5833 | .6667 | .7500 | .8333 | .9167 |
| 1/64 | .0013 | .0846 | .1680 | .2513 | .3346 | .4180 | .5013 | .5846 | .6680 | .7513 | .8346 | .9180 |

## AVOIRDUPOIS WEIGHT
### Short Ton

| | | |
|---|---|---|
| 27.34375 grains (gr.) | = 1 dram | dr. |
| 16 drams | = 1 ounce | oz. |
| 16 ounces | = 1 pound | lb. |
| 100 pounds | = 1 hundredweight | cwt. |
| 20 hundredweight }<br>2,000 pounds } | = 1 ton | T. |

| gr. | dr. | oz. | lb. | cwt. | T. |
|---|---|---|---|---|---|
| 1 = | .036571 = | .002286 = | .000143 = | .000001 | |
| 27.34375 = | 1 = | .062500 = | .003906 = | .000039 = | .000002 |
| 437.5 = | 16 = | 1 = | .062500 = | .000625 = | .000031 |
| 7,000 = | 256 = | 16 = | 1 = | .010000 = | .000500 |
| 700,000 = | 25,600 = | 1,600 = | 100 = | 1 = | .050000 |
| 14,000,000 = | 512,000 = | 32,000 = | 2,000 = | 20 = | 1 |

The ton of 2,000 lb. is the trade standard of the United States, except in transactions involving anthracite (in Pennsylvania) and certain iron and steel products in bulk. A hundredweight is sometimes known as a quintal and is not uncommonly used among fishermen. The dram is practically obsolete.

## Long Ton

The grains, drams, ounces, and pounds are the same as in the short ton.

| | |
|---|---|
| 16 ounces..............| = 1 pound............lb. |
| 14 pounds............| = 1 stone..............st. |
| 2 stones............| = 1 quarter............qr. |
| 4 quarters............| = 1 hundredweight.....cwt. |
| 20 hundredweight.....| = 1 ton (2,240 lb.)......T. |

| oz. | lb. | st. | qr. | cwt. | T. |
|---|---|---|---|---|---|
| 1 = | .062500 = | .004464 = | .002232 = | .000558 = | .000028 |
| 16 = | 1 = | .071429 = | .035714 = | .008929 = | .000446 |
| 224 = | 14 = | 1 = | .500000 = | .125000 = | .006250 |
| 448 = | 28 = | 2 = | 1 = | .250000 = | .012500 |
| 1,792 = | 112 = | 8 = | 4 = | 1 = | .050000 |
| 35,840 = | 2,240 = | 160 = | 80 = | 20 = | 1 |

Short tons multiplied by 1.12 equal long tons. Long tons multiplied by .892857 equal short tons. The long ton is the standard in Great Britain and colonies, except Canada, but its use in the United States is limited. The long ton is used in estimating custom duties.

---

# MEASURES OF VOLUME

| | |
|---|---|
| 1,728 cubic inches (cu. in.).....| = 1 cubic foot .....cu. ft. |
| 27 cubic feet .............| = 1 cubic yard.....cu. yd. |

| cu. in. | cu. ft. | cu. yd. |
|---|---|---|
| 1 = | .000579 = | .000021 |
| 1,728 = | 1 = | .037037 |
| 46,656 = | 27 = | 1 |

A *cord of wood* is 128 cu. ft., or a pile 8 ft. long and 4 ft. high when cut in 4-ft. lengths. It is used in estimating amounts of fire and pulp wood, tanbark, etc.

A ton (2,240 lb.) of Pennsylvania anthracite, when broken for domestic use, occupies about 42 cu. ft. of space; bituminous coal about 46 cu. ft.; and coke, about 88 cu. ft.

A bushel of coal is 80 lb. in Kentucky, Illinois, and Missouri; 76 lb. in Pennsylvania and Montana; and 70 lb. in Indiana.

**Masonry.**—A perch of masonry is 24.75 cu. ft., or is a section of wall 16.5 ft. (1 rd. or perch) long, 1.5 ft. thick, and 1 ft. high. It is very frequently taken as 25 cu. ft. Methods and customs of estimating masonry vary locally and it is highly advisable, when preparing contract specifications, to insert in the agreement, upon what basis the measurements are to be made; that is, if by the perch, the number of cubic feet therein. Owing to the confusion in the dimensions of the perch, the term is falling into disuse, and contracts specify measurements either in cubic feet or cubic yards.

Masonry is measured solid, no deductions being made for corners, which are counted twice, or for openings under 3 ft. in width. This is the custom of the trade and holds in law unless the contract specifies differently. Thus, a foundation wall 1 ft. thick, 8 ft. high, and with outside dimensions of 10 ft. by 12 ft., and with one door opening 2 ft. wide and 8 ft. high, actually contains $[(12 \times 2) + (10 - 1 - 1) \times 2] \times 8 - (2 \times 8) = 304$ cu. ft. On the trade basis, the door opening is neglected and the four side walls are counted at their total length (2 of 12 ft., and 2 of 10 ft.), and the wall contains $[(12 \times 2) + (10 \times 2)] \times 8 = 352$ cu. ft.

**Brickwork.**—Brickwork is generally estimated by the thousand bricks laid in the wall, but measurements by the cubic foot and the perch are also used. When making calculations of the volume of walls, etc., to allow for mortar, it is customary to add ¼ in. to the length and thickness of each brick. The following data will be useful in calculating the number of bricks in a wall. For each superficial foot of wall 4 in. in thickness (the width of one brick), allow 7½ bricks; for a 9-in. wall (the width of two bricks), allow 15 bricks; and so on, estimating 7½ bricks for each additional 4 in. in thickness of wall. If brickwork is estimated by the cubic yard, allow 500 bricks to 1 cu. yd. This figure is based on the use of a 8¼ in. by 4 in. by 2¼ in. brick, with mortar joints not over ⅜ in. thick. If the joints are ¼ in. thick, as in face brickwork, 1 cu. yd. will require about 575 bricks. An allowance of 5% should be made for waste in breakage, etc.

**Shipping.**—The *gross tonnage* of a ship is its entire internal capacity, calculated according to certain rather complicated rules laid down in the Revised Statutes of the United States. The *net tonnage* of a ship is obtained by deducting from the gross tonnage the space given over to engines, coal, quarters for the crew, etc.; that is, it is the net space available for cargo or paying load. *Registered tonnage* is the entire internal cubic contents of the vessel divided by 100, or 100 cu. ft. equals 1 registered ton. The term gives no idea of the dimensions of the vessel, and is merely an arbitrary way of forming some conception of its relative size.

*Displacement* is the weight of the volume of water displaced by the hull of a vessel and is often confused with some one of the meanings of tonnage just given. The displacement of a ship naturally varies, depending on the weight of cargo, stores, fuel, etc., aboard. Thus, the displacement of a transatlantic liner will be markedly less on arriving at New York than when leaving England. Displacement is frequently calculated at a *normal*, or standard, depth of water, to which draft the ship is usually loaded, or for which it was designed; from this is derived the expression, say, "displacement 18,500 T. on 23 ft. draft."

For the purpose of calculating vessel freights, estimating stowage capacity, etc., 1 U. S. *shipping ton* equals 40 cu. ft. and is equivalent to 32.143 U. S. bu., or 31.16 imp. bu. of England. The British shipping ton is 42 cu. ft. and is equal to 32.719 imp. bu., or 33.75 U. S. bu.

For weights of various materials see under the heading Specific Gravity.

## LIQUID MEASURE

By act of Congress the standard of liquid measure is the *gallon* of 231 cu. in.

| | | | |
|---|---|---|---|
| 1 gill | gi. | 7.21875 cu. in. |
| 4 gills | = 1 pint | pt. | 28.875 cu. in. |
| 2 pints | = 1 quart | qt. | 57.750 cu. in. |
| 4 quarts | = 1 gallon | gal. | 231.000 cu. in. |
| 31.5 gallons | = 1 barrel | bbl. | 4.211 cu. ft. |
| 2 barrels | = 1 hogshead | hhd. | 8.422 cu. ft. |

| *gi.* | *pt.* | *qt.* | *gal.* | *bbl.* | *hhd.* |
|---|---|---|---|---|---|
| 1 | = .250 | = .125 | = .03125 | = .000992 | = .000496 |
| 4 = | 1 | = .500 | = .12500 | = .003968 | = .001984 |
| 8 = | 2 = | 1 | = .25000 | = .007936 | = .003968 |
| 32 = | 8 = | 4 = | 1 | = .031746 | = .015873 |
| 1,008 = | 252 = | 126 = | 31.5 = | 1 | = .500000 |
| 2,016 = | 504 = | 252 = | 63 = | 2 = | 1 |

The U. S. liquid pint, quart, and gallon are equal, respectively, to .85937 U. S. dry pint, quart, and gallon. The U. S. dry pint, quart, and gallon are equal, respectively, to 1.16365 U. S. liquid pint, quart, and gallon.

A box 19⅜ in. long on each edge contains 1 bbl.

In approximate calculations, 1 cu. ft. of water may be considered equal to 7½ gal., and 1 gal. as weighing 8⅓ lb.

The capacity of a cylinder in U. S. liquid gallons = square of the diameter, in inches × height, in inches × .0034 (accurate within 1 part in 100,000).

The following cylinders contain the given measures very closely:

| | Diam. Inches | Height Inches | | Diam. Inches | Height Inches |
|---|---|---|---|---|---|
| Gill | 1½ | 3 | Gallon | 7 | 6 |
| Pint | 3½ | 3 | 8 gal. | 14 | 12 |
| Quart | 3½ | 6 | 10 gal. | 14 | 15 |

## DRY MEASURE

By act of Congress the standard of dry measure is the bushel defined as a cylinder 18½ in. in diameter, 8 in. deep, and containing 2,150.42 cu. in.

| | | | |
|---|---|---|---|
| 1 pint | pt. | 33.6003125 cu. in. |
| 2 pints | = 1 quart | qt. | 67.200625 cu. in. |
| 4 quarts | = 1 gallon | gal. | 268.8025 cu. in. |
| 2 gallons | = 1 peck | pk. | 537.605 cu. in. |
| 4 pecks | = 1 bushel | bu. | 2,150.42 cu. in. |

|  | pt. | qt. | gal. | pk. | bu. |
|--|--|--|--|--|--|
| 1 = | .500 = | .125 = | .0625 = | .015625 |
| 2 = | | 1 = | .250 = | .1250 = | .031250 |
| 8 = | | 4 = | 1 = | .5000 = | .125000 |
| 16 = | | 8 = | 2 = | 1 = | .250000 |
| 64 = | | 32 = | 8 = | 4 = | 1 |

The standard bushel is a *struck.*, or level full, *bushel.* The *heaped bushel* is approximately equal to 1¼ struck bu., the *cone*, or heap, being not less than 6 in. in height.

The standard bushel is equal to 1.24445, or approximately 1¼, cu. ft. 1 cu. ft. is equal to .80356, or approximately ⅘, bu.

A cube 3.227 in. on an edge contains 1 pt.; one 4.066 in. on an edge, 1 qt.; one 6.454 in. on an edge, 1 gal.; one 8.131 in. on an edge, 1 pk.; and one 12.908 in. on an edge, 1 bu.

The capacity of a cylinder in U. S. bushels = square of diameter in inches ×height in inches×.0003652.

There appears to be no standard barrel, dry measure, although one of 3 struck bu. is frequently recognized.

The relation between the dimensions of the units of dry and liquid measure will be found under the former.

## RELATION BETWEEN VOLUMES AND WEIGHTS OF WATER, U. S. LIQUID MEASURE

The mass of a given volume of water, such as 1 cu. ft. or 1 gal., depends on the conditions under which it is weighed, being less if weighed in air than in a vacuum, at the equator than at the poles, at sea level than at any elevation above, and at higher than at lower readings of either the thermometer or barometer. Reduced from the French measurements made to determine the relations existing between the units of the metric system, the weight *in vacuuo* of 1 cu. ft. of pure distilled water, free from air, at the temperature of its maximum density (4° C., or 39.3° F.) and under a barometric pressure of 760 millimeters (29.92 in.) of mercury, at sea level and at the latitude of Paris (48° 50′ N), is 62.42664 lb. This is the weight commonly used in pocketbooks and is often given as 62.427 lb., 62.43 lb., and even as 62.5 lb., depending on the degree of accuracy required. From this, the weight of 1 cu. in. of water under the given conditions may be taken as .036126 lb., .036 lb., or even .04 lb. At other temperatures commonly used in calculations the weight of 1 cu. ft. of water is: at 32° F., 62.418 lbs.; at 62° F., 62.355 lbs.; and at 212° F., 59.846 lbs.

The following table gives the weight *in air* of 1 gal. and of 1 cu. ft. of distilled water. These weights are reduced from the French measurements and are referred to sea level at the latitude of Paris. They represent the customary or ordinary manner of weighing.

| Temperature | Pressure | Weight of 1 Gal. Pounds | Weight of Cu. Ft. Pounds |
|--|--|--|--|
| 4° C. (39.3° F.)..760 mm. (29.92 in.)... | .8.33586..... | 62.35656 |
| 62° F. (16.7° C.)..760 mm. (29.92 in.)... | .8.32675..... | 62.28844 |
| 62° F. (16.7° C.).. 30 in. (762.0 mm.)... | .8.32673..... | 62.28827 |

The following table of equivalents is based upon the weight of 1 cu. ft. of water *weighed in air* at 39.3° F., and 29.92 in. of mercury, viz.: 62.356562 lb. avoirdupois.

### EQUIVALENT WEIGHTS AND VOLUMES OF WATER

| Gills | Pints | Quarts | Gallons | Cubic Inches | Cubic Foot | Weight of Water Pounds |
|--|--|--|--|--|--|--|

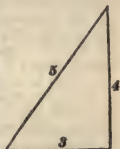
## ANGULAR, OR CIRCULAR, MEASURE

60 seconds (sec. or ″) ..... = 1 minute............min. or ′
60 minutes..... ......... = 1 degree...........deg. or °
360 degrees............... = 1 circumference .... cir.

| sec. | min. | deg. | cir. |
|------|------|------|------|
| 1 = | .016667 = | .000278 = | .000008 |
| 60 = | 1 = | .016667 = | .000463 |
| 3,600 = | 60 = | 1 = | .002778 |
| 1,296,000 = | 21,600 = | 360 = | 1 |

For tables of grades, grade angles, etc., see under the head of Tracklaying.

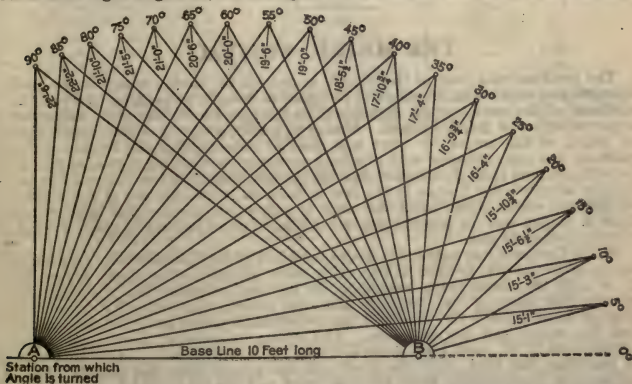
**Laying Off Right Angles.**—Right angles may conveniently be laid off in the field by using the relation existing between the hypotenuse and sides of a right-angled triangle, viz.: The square of the hypotenuse is equal to the sum of the squares of the sides. The commonly used ratio is 3 for the horizontal side, 4 for the vertical side, and 5 for the hypotenuse, or slope. There are many other ratios, such as 8, 15, 17, and the like, a number of which are given in the following table. Likewise, any multiple or submultiple of these ratios may be used. Thus, instead of 3, 4, and 5, $\frac{1}{2}$, $1\frac{1}{2}$, or 2 times the proportion may be used, as 1.5, 2, 2.5, or 4.5, 6, 7.5, or 6, 8, and 10, respectively.


### RATIO OF SIDES OF RIGHT-ANGLED TRIANGLE

| Hori-zontal | Verti-cal | Slope | Hori-zontal | Verti-cal | Slope | Hori-zontal | Verti-cal | Slope |
|---|---|---|---|---|---|---|---|---|
| 3 | 4 | 5 | 12 | 16 | 20 | 18 | 24 | 30 |
| 4 | 3 | 5 | 12 | 9 | 15 | 20 | 15 | 25 |
| 6 | 8 | 10 | 14 | 48 | 50 | 20 | 48 | 52 |
| 7 | 24 | 25 | 15 | 8 | 17 | 24 | 32 | 40 |
| 8 | 6 | 10 | 15 | 20 | 25 | 24 | 18 | 30 |
| 8 | 15 | 17 | 15 | 36 | 39 | 24 | 45 | 51 |
| 9 | 12 | 15 | 16 | 12 | 20 | 24 | 7 | 25 |
| 10 | 24 | 26 | 16 | 30 | 40 | 25 | 60 | 65 |

**Laying Off an Angle With a Tape.**—It is frequently necessary to lay off other than right angles as, for example, when a cut or two must be taken from

Base Line 10 Feet long

Station from which Angle is turned


the rib of an entry at a point where a branch entry is to be started, in order that there may be room to place the sights. Suppose it is desired to turn an angle

of 50° to the left.   Fasten the 0 end of an ordinary tape at *A*, then stretch the tape to *B* a distance of 10 ft., and fasten the 10-ft. mark at *B*.   If the angle is to be turned from an entry, the points *A* and *B* can be lined in from the entry sights.   Then fasten the 30-ft. mark of the tape at *A*.   This will leave 20 ft. of slack tape between *A* and *B*.   Find the 19-ft. mark on the tape, and draw the tape tight from both *A* and *B*.   The tape line from *A* to the 19-ft. mark will make an angle of 50° at *A* with the line *A B*.   If the angle is to the right, use the same measurements to the right of the base line.   For other angles than 50° hold the tape at the mark given, on the accompanying diagram, below the required number of degrees.   Thus, for 75°, hold the tape at the 21′ 5″ mark; for 30°, hold it at the 16′ 9¾″ mark, and similarly for other angles.

---

## MEASURE OF TIME

| | | | |
|---|---|---|---|
| 60 seconds (s.) . . . . . | = 1 minute | . . . . min. or $^m$ |
| 60 minutes . . . . . . . . | = 1 hour | . . . . . . . . hr. or $^h$ |
| 24 hours . . . . . . . . . . | = 1 day | . . . . . . . . . da. or $^d$ |

|   sec.   |   min.   |   hr.   |   da.   |
|---|---|---|---|
| 1 = | .016667 = | .000278 = | .000012 |
| 60 = | 1 = | .016667 = | .000694 |
| 3,600 = | 60 = | 1 = | .041667 |
| 86,400 = | 1,440 = | 24 = | 1 |

Solar, astronomical, civil, and standard time are discussed in the chapter on Surveying under the heading Determination of the Meridian.

### LONGITUDE AND TIME

As the earth makes a complete revolution of 360° upon its axis in 24 hr., degrees, minutes, and seconds of arc, or longitude, may be expressed in hours, minutes, and seconds of time.

| *Arc = Time* | *Arc = Time* |
|---|---|
| 360 degrees = 24 hours | 1 minute = 4 seconds |
| 15 degrees = 1 hour | 15 seconds = 1 second |
| 1 degree = 4 minutes | 1 second = .0666+ second |
| 15 minutes = 1 minute | |

---

## THE METRIC SYSTEM

The fundamental unit of the metric system is the *meter*, which is the unit of length and which was intended to be equal in length to $\frac{1}{10000000}$ part of the quadrant of the earth, or the distance from the equator to the pole, measured on the meridian of Paris, France.   Owing to imperfection in instruments, etc., the length of the arc of 10° that was used in determining the length of the quadrant was not measured with absolute accuracy, so that the meter, as well as the units derived from it, is not of exactly the dimensions it was intended to be. Since its adoption by France in the law of June 22, 1799, the use of the system has become world wide, until the only countries of commercial importance where it is not now in general use are China, Great Britain, Japan, Russia, and the United States.

While Congress has authority, under Article I of the Constitution, to compel the use of the metric system, it has never done so, contenting itself, under the act of July 28, 1866, with legalizing its use and establishing the relations between the units of the ordinary and the metric systems.   By Executive Order of April 5, 1893, the yard and the avoirdupois pound may now be derived from the meter and the kilogram.   The ratios established by Congress are 1 meter = 39.37 in., and 1 kilogram = 2.2046 lb. avoirdupois.   As these values are less than the true ones, the yard and the pound thus derived are longer and heavier, respectively, than the true yard and the true pound.

The names applied to the various denominations of the system are not always those used in France, but are frequently adapted from the names of

the measures that the metric system has displaced. In almost all of these countries the old and replaced systems are still in use, the extent of this usage being, apparently, in inverse ratio to the commercial importance of the country and to the length of time during which the metric system has been in force.

The original standards of the metric system were a meter and a kilogram of platinum deposited in the Palais des Archives, Paris, at the time of the formal adoption of this system in France. At the second meeting of what is now the International Bureau of Weights and Measures, held in Paris, Sept. 24, 1872, the representatives of thirty nations present decided that the standards of the system should be made of an alloy of 90% platinum and 10% iridium, because of its hardness, fine grain, and ability to withstand the action of acids. A number of meters and kilograms were made and the ones corresponding to the original platinum standards are deposited in the permanent headquarters of the bureau, near Paris. Each nation subscribing to the expenses of the bureau received two copies each of the meter and the kilogram, which are known, respectively, as the *national prototype meter and kilogram*. These are of the same materials and accuracy as the originals. The United States prototypes were received by the President on Jan. 2, 1890, and one of each was selected as a reference standard, while the other is used for working purposes.

The unit of weight of the metric system is the *kilogram*, originally intended to be the weight, in vacuuo, of 1 cubic decimeter of pure, distilled water at the temperature of its maximum density, 4° C. (39.3° F.), with the barometer at 760 millimeters (29.92 in.) of mercury. As with the meter, this relation is not exact, owing to errors in the original standard.

The unit of capacity is the *liter*, which was designed to be the volume of 1 kilogram of pure water under the conditions just named.

The unit of area for land measure is the *are*, a square 10 meters on the side. Among engineers, superficial dimensions are usually expressed in square centimeters, square meters, and square kilometers.

Cubic dimensions are expressed in cubic centimeters, cubic meters, etc.

Multiples of the various units of the metric system are obtained by prefixing to the names of the units (meter, gram, and liter) the Greek words, *deka* or *deca* (10), *hekto* or *hecto* (100), *kilo* (1,000), and *myria* (10,000). The submultiples or divisions are obtained by prefixing to the names of the units, the Latin words *deci* ($\frac{1}{10}$), *centi* ($\frac{1}{100}$), and *milli* ($\frac{1}{1000}$).

### METRIC MEASURES OF LENGTH

| | | | |
|---|---|---|---|
| 1 millimeter | | mm. | .001 |
| 10 millimeters | = 1 centimeter | cm. | .01 |
| 10 centimeters | = 1 decimeter | dm. | .1 |
| 10 decimeters | = 1 meter | m. | 1 |
| 10 meters | = 1 dekameter | Dm. | 10 |
| 10 dekameters | = 1 hektometer | Hm. | 100 |
| 10 hektometers | = 1 kilometer | Km. | 1,000 |
| 10 kilometers | = 1 myriameter | Mm. | 10,000 |

Of these denominations the ones commonly employed are the millimeter, centimeter, meter, and kilometer. The United States Coast and Geodetic Survey, since 1884, has used the value 1 m. = 39.370432 in.; the legal equivalent by Act of Congress is 1 m. = 39.37 in.

### METRIC MEASURES OF SURFACE

| | | | |
|---|---|---|---|
| 1 sq. millimeter | | sq. mm., or mm.² | .000001 |
| 100 sq. millimeters | = 1 sq. centimeter | sq. cm., or cm.² | .0001 |
| 100 sq. centimeters | = 1 sq. decimeter | sq. dm., or dm.² | .01 |
| 100 sq. decimeters | = 1 sq. meter | sq. m., or m.² | 1 |
| 100 sq. meters | = 1 sq. dekameter | sq. Dm., or Dm.² | 100 |
| 100 sq. dekameters | = 1 sq. hektometer | Hm., or Hm.² | 10,000 |
| 100 sq. hektometers | = 1 sq. kilometer | sq. Km., or Km.² | 1,000,000 |
| 100 sq. kilometers | = 1 sq. myriameter | sq. Mm., or Mm.² | 100,000,000 |

The square meter is sometimes known as the *centare;* the square dekameter as the *are;* and the square hektometer as the *hectare.* Farm measurements are generally given in hectares. Engineers use the square millimeter, square centimeter, square meter, and square kilometer. The other denominations are but little used. The square meter, or centare, is a little larger than 1 sq. yd.; the hektometer, or hectare, is about 2½ A.

### METRIC MEASURES OF WEIGHT

| | | | |
|---|---|---|---:|
| 1 milligram | | mg. | .001 |
| 10 milligrams | =1 centigram | cg. | .01 |
| 10 centigrams | =1 decigram | dg. | .1 |
| 10 decigrams | =1 gram | g. | 1 |
| 10 grams | =1 dekagram | Dg. | 10 |
| 10 dekagrams | =1 hektogram | Hg. | 100 |
| 10 hektograms | =1 kilogram | Kg. | 1,000 |
| 10 kilograms | =1 myriagram | Mg. | 10,000 |
| 10 myriagrams | =1 quintal | Q. | 100,000 |
| 10 quintals | =1 tonne | T. | 1,000,000 |

The denominations in common use are the milligram, centigram, gram, kilogram (commonly called kilo), and tonne. Commercially, the kilogram is divided into halves, quarters, etc. As near as may be determined, 1 Kg. =2.2046223 lb. avoirdupois. The ratio legalized by Congress is 1 Kg.=2.2046 lb. avoirdupois.

### METRIC MEASURES OF VOLUME

| | | | |
|---|---|---|---:|
| 1 cubic millimeter | | cu. mm., or mm.$^3$ | .000000001 |
| 1,000 cubic millimeters | =1 cubic centimeter | c.c., cc.$^3$, or cu. cm. | .000001 |
| 1,000 cubic centimeters | =1 cubic decimeter | cu. dm., or dm.$^3$ | .001 |
| 1,000 cubic decimeters | =1 cubic meter | cu. m., or m.$^3$ | 1 |

The cubic millimeter and cubic decimeter are rarely used. The cubic centimeter is a common unit with chemists, and engineers use the cubic meter in the same way as the cubic yard.

### METRIC MEASURES OF CAPACITY

| | | | |
|---|---|---|---:|
| 1 milliliter | | ml. | .001 |
| 10 milliliters | =1 centiliter | cl. | .01 |
| 10 centiliters | =1 deciliter | dl. | .1 |
| 10 deciliters | =1 liter | l. | 1 |
| 10 liters | =1 dekaliter, or | Dl. | 10 |
| | 1 centistere | cs. | |
| 10 dekaliters | =1 hektoliter, or | Hl. | 100 |
| | 1 decistere | ds. | |
| 10 hektoliters | =1 kiloliter, or | Kl. | 1,000 |
| | 1 stere | s. | |
| 10 kiloliters | =1 myrialiter, or | Ml. | 10,000 |
| | 1 dekastere | Ds. | |

The liter and the milliliter (but in its equivalent form the cubic centimeter) are in use among chemists. Engineers use the liter and kiloliter, the latter being called by its equivalent name, cubic meter. Groceries and the like are purchased by the liter, half liter, and quarter liter, instead of by the decimal parts of a liter. Grain is measured by the stere and by the decistere, the latter being called hektoliter.

Congress has not established a ratio between the units of the measures of capacity of the metric and ordinary systems.

### EQUIVALENTS OF VOLUME, WEIGHT OF WATER, AND CAPACITY

Distilled water at 4° C. (39.3° F.) and 760 mm. (29.92 in.) pressure.

| *Volume* | *Weight* | *Capacity* | *Ratio* |
|---|---|---|---:|
| 1 cubic centimeter | =1 gram | =1 milliliter | 1 |
| 10 cubic centimeters | =1 decagram | =1 centiliter | 10 |
| 100 cubic centimeters | =1 hektogram | =1 deciliter | 100 |
| 1 cubic decimeter | =1 kilogram | =1 liter | 1,000 |
| 10 cubic decimeters | =1 myriagram | =1 dekaliter | 10,000 |
| 100 cubic decimeters | =1 quintal | =1 hektoliter | 100,000 |
| 1 cubic meter | =1 tonne | =1 stere | 1,000,000 |

The United States 50c. silver coin weighs 12.5 g.; the 25c. coin, 6.25 g.; and the 10c. coin, 2.5 g. These weights have been assigned by congressional enactment.

---

# WEIGHTS AND MEASURES OF GREAT BRITAIN AND COLONIES

The measures of length, of surface, of weight, and of volume, while not absolutely identical, are, for all practical purposes, the same as those of the United States. It should be noted, however, that the United States long ton of 2,240 lb. is used in Great Britain and all of her colonies, except Canada, where the ton has been fixed by statute at 2,000 lb. The quarter of 28 lb. and the stone of the 14 lb. are used to some extent.

The chief difference between the measures of Great Britain and the United States is to be found in the sizes of the units of dry and liquid measure. The United States liquid gallon is, by Act of Congress, equal to 231 cu. in., and the United States bushel is, by similar enactment, equal to 2,150.42 cu. in., no reference being made to the weight of water contained in either of the measures. They were founded upon the former British wine gallon and the Winchester *struck* (level full) *bushel*, which have not been current in Great Britain since 1825, when they were replaced by the imperial gallon and bushel. By Act of Parliament, the imperial gallon is the volume of 10 lb. of pure water at 62° F., weighed against brass weights in air at the same temperature and at a barometric pressure of 30 in. of mercury. The imperial bushel is the volume of 80 lb. of pure water under the preceding conditions. From this, it is apparent that the imperial gill, pint, quart, and gallon, are the same in both the liquid and dry measure.

Using the value for the weight of 1 cu. ft. of water, 62.28827 lb., the volume of the imperial gallon is found to be 277.4203 cu. in., and of the imperial bushel, 2,219.3613 cu. in.

### IMPERIAL MEASURE, BOTH LIQUID AND DRY

| | | | Volume Cubic Inches | Weight of Water Pounds |
|---|---|---|---|---|
| 1 gi. | | = | 8.8694 | = .3125 |
| 4 gi. | = 1 pt. | = | 34.6775 | = 1.2500 |
| 2 pt. | = 1 qt. | = | 69.3551 | = 2.5000 |
| 4 qt. | = 1 gal. | = | 277.4203 | = 10.0000 |
| 2 gal. | = 1 pk. | = | 554.8403 | = 20.0000 |
| 4 pk. | = 1 bu. | = | 2,219.3613 | = 80.0000 |

One imp. gal. equals 1.20095 U. S. liquid gal., and 1 imp. bu. equals 1.03206 U. S. bu. Likewise, 1 U. S. liquid gal. equals .83267 imp. gal., and 1 U. S. bu. equals .96894 imp. bu.

Fineness expresses the proportion of pure metal in 1,000 parts; thus, "900 fine" means that 900 of every 1,000 parts are pure metal. Fineness of U. S. coins=900 pure metal, 100 alloy; alloy of gold coin is copper or copper and silver, but in no case shall silver exceed one-tenth of total alloy. Alloy of silver coin is copper.

| Turkey | 40 paras = 1 piastre | .0439 |
| Uruguay[7] | 100 centesimos = 1 peso | .9647 |
| Venezuela | 100 centimos = 1 bolivar | .1929 |

[1] The actual currency is either depreciated or inconvertible paper of fluctuating value. The values given are for the standard gold coin.

[2] This is the new coinage. The former *tael* is still largely used. Its value differs from town to town and ranges between $.599 at Shanghai to $.660 at Takau. The Haikwan, or tael in which customs are payable, is valued at $.667. The Hong Kong and British dollar, valued at $.431, and the Mexican dollar, valued at $.434, circulate widely.

[3] Cuba has no national currency, gold, silver, or paper, relying upon the money of the United States, Great Britain, and Spain for its needs.

[4] The actual standard is the pound sterling of Great Britain.

[5] Fifteen rupees equal 1 pound sterling.

[6] The values given are for the gold kran and peseta respectively. The actual currency is silver circulating above its metallic value.

[7] The value given is for the silver peso. While under the gold standard, Uruguay has never coined this metal. The standard value of the gold peso is $1.0342.

# ARITHMETIC
## COMMON FRACTIONS

**To Add Fractions.**—If the fractions are of the same denominator, add together the numerators only. Thus, $\frac{1}{8} + \frac{3}{8} + \frac{5}{8} = \frac{9}{8} = 1\frac{1}{8}$.

If they have different denominators, change them to fractions with common denominators, and proceed as before. Thus, $\frac{1}{2} + \frac{1}{4} + \frac{2}{5} = \frac{20}{40} + \frac{10}{40} + \frac{24}{40} = \frac{53}{40}$.

**To Subtract Fractions.**—If the fractions are of the same denominator, subtract the lesser numerator from the greater. Thus, $\frac{7}{16} - \frac{3}{16} = \frac{4}{16} = \frac{1}{4}$.

If they have different denominators, change them to fractions with common denominators, and proceed as before. Thus, $\frac{7}{8} - \frac{2}{3} = \frac{21}{24} - \frac{16}{24} = \frac{5}{24}$.

**To Multiply Fractions.**—Multiply the numerators together for the numerator, and the denominators for the denominator. Thus, $\frac{3}{4} \times \frac{7}{16} \times \frac{2}{3} = \frac{42}{192} = \frac{7}{32}$.

**To Divide Fractions.**—Invert the divisor and multiply. Thus, to divide $\frac{9}{64}$ by $\frac{2}{3}$ the $\frac{2}{3}$ is inverted, and $\frac{9}{64} \div \frac{2}{3} = \frac{9}{64} \times \frac{3}{2} = \frac{27}{128}$.

**To Reduce Compound Fractions to Simple Fractions.**—Multiply the integer by the denominator of the fraction, add the numerator for the new numerator, and place it over the denominator.

EXAMPLE.—Reduce $5\frac{2}{3}$ to a simple fraction.

SOLUTION.— $(5 \times 3) + 2 = 17$, the numerator, the fraction is therefore $\frac{17}{3}$.

**To Reduce Simple Fractions to Compound Fractions.**—Divide the numerator by the denominator, and use the remainder as the numerator of the remaining fraction.

EXAMPLE.—Reduce $\frac{64}{9}$ to a compound fraction.

SOLUTION.—   9 ) 6 4 ( 7
             6 3    Compound fraction is $7\frac{1}{9}$
          —
          1

**To Reduce Common Fractions to Decimal Fractions.**—Annex ciphers to the numerator, and divide by the denominator, and point off as many decimal places in the quotient as there are ciphers annexed.

EXAMPLE.—Reduce $\frac{9}{16}$ to a decimal fraction.

SOLUTION.—               1 6 ) 9.0 0 0 0 (.5 6 2 5
                     8 0
                   —
               1 0 0
                9 6
               —
              4 0
              3 2
             —
              8 0
              8 0

NOTE.—Ciphers annexed to a decimal do not increase its value. 1.13 is the same as 1.1300. Every cipher placed between the first figure of a decimal and the point divides the decimal by 10. Thus, .13 ÷ 10 = .013.

## DECIMALS

*Decimals* are fractions that have for their denominators 10 or a power of 10, but the denominator is usually omitted. Thus, $.1 = \frac{1}{10}$; $.01 = \frac{1}{100}$; $.001 = \frac{1}{1000}$, etc.

**To Add Decimals.**—Place whole numbers under whole numbers, tenths under tenths, hundredths under hundredths, etc., and add, placing the decimal point in the sum directly under the points above. Thus,

```
        .0 0 7 5
        .6 3
       1.0 6
      17.9 3 4 2
      ──────────
      19.6 3 1 7
```

**To Subtract Decimals.**—Arrange the figures as in addition, and proceed as in simple subtraction. Thus,

```
       5.9 6 9 7 8
       3.2 8 6 9 4
       ──────────
       2.6 8 2 8 4
```

**To Multiply Decimals.**—Proceed as in simple multiplication, pointing off as many decimal places in the result as there are decimal places in both multiplicand and multiplier. Thus,

```
      4.6 7 5 3 1   (5 decimal places)
        .0 5 3       (3 decimal places)
      ───────────
      1 4 0 2 5 9 3
    2 3 3 7 6 5 5
    ─────────────────
    .2 4 7 7 9 1 4 3   (8 decimal places)
```

**To Divide Decimals.**—Proceed as in simple division, and point off as many decimal places in the quotient as the number of decimal places in the dividend exceeds those in the divisor.

EXAMPLE 1.—Divide 4.756 by 3.3.

SOLUTION.—

```
      3.3 ) 4.7 5 6 0 0 ( 1.4 4 1 2
            3 3
            ───
            1 4 5
            1 3 2
            ─────
              1 3 6
              1 3 2
              ─────
                4 0
                3 3
                ───
                7 0
                6 6
                ───
                4
```

EXAMPLE 2.—Divide .006 by 20.

SOLUTION.—

```
      2 0 ) .0 0 6 0 ( .0 0 0 3
              6 0
```

**To Reduce Decimals to Common Fractions.**—Omit the decimal point and use the figures thus obtained for the numerator. The denominator will be 1 with as many ciphers attached as there are places after the decimal point and will always be 10 or some multiple thereof. Reduce the fraction thus obtained to its lowest terms. Thus, in the form of a common fraction, the decimal .025 = $\frac{025}{1000} = \frac{25}{1000} = \frac{1}{40}$.

## FORMULAS

The term *formula*, as used in mathematics and in technical books, may be defined as a rule in which symbols are used instead of words; in fact, a formula may be regarded as a shorthand method of expressing a rule.

The well-known rule for finding the indicated horsepower of a steam engine may be stated as follows:

*Divide the continued product of the mean effective pressure, in pounds per square inch, the length of the stroke, in feet, the area of the piston, in square inches, and the number of strokes per minute by 33,000; the result will be the horsepower.*

An examination of the rule will show that four quantities (viz., the mean effective pressure, the length of the stroke, the area of the piston, and the number of strokes) are multiplied together, and the result is divided by 33,000. Hence, the rule might be expressed as follows:

$$\text{Horsepower} = \frac{\text{mean effective pressure}}{\text{(in pounds per square inch)}} \times \frac{\text{stroke}}{\text{(in feet)}}$$
$$\times \frac{\text{area of piston}}{\text{(in square inches)}} \times \frac{\text{number of strokes}}{\text{(per minute)}} \div 33,000$$

This expression may be shortened by representing each quantity by a single letter, thus: representing horsepower by the letter $H$, the mean effective pressure in pounds per square inch by $P$, the length of the stroke in feet by $L$, the area of the piston in square inches by $A$, the number of strokes per minute by $N$, and substituting these letters for the quantities that they represent, the foregoing expression will reduce to

$$H = \frac{P \times L \times A \times N}{33,000},$$

a much simpler and shorter expression. This last expression is called a formula.

It is customary, however, to omit the sign of multiplication between two or more quantities when they are to be multiplied together, or between a number and a letter representing a quantity, it being always understood that when two letters are adjacent with no sign between them, the quantities represented by these letters are to be multiplied. Bearing this fact in mind, the formula just given can be further simplified to

$$H = \frac{P\,L\,A\,N}{33,000}$$

## PROPORTION, OR CAUSE AND EFFECT

*Ratio* is the relation of one number to another as obtained by dividing one by the other. The ratio of 8 to 4 is $8 \div 4 = 2$.

*Simple proportion* is the expression of equality between equal ratios; thus, the ratio of 10 to 5 is 2 and the ratio of 4 to 2 is, also, 2. The relations between these are expressed thus, $10 : 5 :: 4 : 2$, or as $10 : 5 = 4 : 2$. The equality sign ($=$) being easier to write than the double colon ($::$) is the form commonly used.

Proportions may also be expressed as fractions. The preceding ratio, $10 : 5 = 4 : 2$, may be written $\frac{10}{5} = \frac{4}{2}$.

There are four terms in every proportion. The first and last terms are the *extremes*, and the second and third terms are the *means*.

In the ratio $10 : 5$ the first term, 10, is the *antecedent*, and the second term, 5, is the *consequent*. In the question "If 10 men earn \$20, how much will 30 men earn?" which may be expressed in the form $10 : 20 = 30 : y$ ($y$ representing the unknown amount the 30 men will earn), the number of men, 10 and 30, are the *antecedents*, or *causes*, and the sums earned, \$20 and $y$ dollars, are the *consequents* or *effects*.

Quantities are in proportion by *alternation* when antecedent is compared with antecedent and consequent with consequent. Thus, if $10 : 5 = 4 : 2$, then $10 : 4 = 5 : 2$.

Quantities are in proportion by *inversion* when the antecedents are made consequents and the consequents antecedents. Thus, if $10 : 5 = 4 : 2$, then $5 : 10 = 2 : 4$.

In any proportion, the product of the means will equal the product of the extremes. Thus, if $10 : 5 = 4 : 2$, then $5 \times 4 = 10 \times 2$.

A mean proportional between two quantities equals the square root of their product. Thus, a mean proportional between 12 and 3 = the square root of $12 \times 3$, and the proportion is expressed thus, $12 : 6 = 6 : 3$.

If the two means and one extreme of a proportion are given, the other extreme may be found by dividing the product of the means by the given extreme. Thus, $10 : 5 = 4 : (\ )$, then $(4 \times 5) \div 10 = 2$, and the proportion is $10 : 5 = 4 : 2$. This may also be expressed algebraically. If $y =$ the unknown quantity, the proportion is written $10 : 5 = 4 : y$. Then $10 \times y = 5 \times 4$, or $10y = 20$ and $y = 20 \div 10 = 2$, as before.

If the two extremes and one mean are given, the other mean may be found by dividing the product of the extremes by the given mean. Thus, $10 : (\ ) = 4 : 2$, then $(10 \times 2) \div 4 = 5$, and the proportion is $10 : 5 = 4 : 2$. This may be expressed algebraically. Thus, $10 : y = 4 : 2$, or $10 \times y = y \times 4$, or $4y = 20$, and $y = 20 \div 4 = 5$, as before.

EXAMPLE.—If 6 men load 30 cars in 1 da., how many cars will 10 men load?

SOLUTION.—The antecedents, or causes are the number of men and the consequents, or effects, the number of cars loaded by them. If $y$ represents the unknown number of cars loaded by the 30 men, the proportion may be expressed
$$\overset{cause}{6 \text{ (men)}} : \overset{effect}{30 \text{ (cars)}} = \overset{cause}{10 \text{ (men)}} : \overset{effect}{y \text{ (cars)}}.$$
From this, $6 \times y = 30 \times 10$, or $6y = 300$, and $y = 300 \div 6 = 50$, the number of cars loaded by 10 men.

A *compound proportion* is one in which one or both of the ratios contains more than one term. The governing principles are as follows:

1. The product of the simple ratios of the first couplet equals the product of the simple ratios of the second couplet. Thus, $\begin{Bmatrix} 4 : 12 \\ 7 : 14 \end{Bmatrix} = \begin{Bmatrix} 5 : 10 \\ 6 : 18 \end{Bmatrix}$ $=\dfrac{4}{12} \times \dfrac{7}{14} = \dfrac{5}{10} \times \dfrac{6}{18}$.

2. The product of all the terms in the extremes equals the product of all the terms in the means. Thus, in $\begin{Bmatrix} 4 : 12 \\ 7 : 14 \end{Bmatrix} = \begin{Bmatrix} 5 : 10 \\ 6 : 18 \end{Bmatrix}$, $4 \times 7 \times 10 \times 18 = 12 \times 14 \times 5 \times 6$.

3. Any term in either extreme equals the product of the means divided by the product of the other terms in the extremes. Thus, in the same proportion, $4 = \dfrac{5 \times 6 \times 12 \times 14}{7 \times 10 \times 18}$.

4. Any term in either mean equals the product of the extremes divided by the product of the other terms in the means. Thus, in $\begin{Bmatrix} 4 : 12 \\ 7 : 14 \end{Bmatrix} = \begin{Bmatrix} 5 : 10 \\ 6 : 18 \end{Bmatrix}$, $5 = (4 \times 7 \times 10 \times 18) \div (6 \times 12 \times 14)$.

EXAMPLE 1.—If 4 men in 7 da. earn \$24, how much can 14 men earn in 12 da.?

SOLUTION.—Here the antecedents, or causes, are the men and the number of days they worked and the consequents, or effects, are the sums of money they earned. If $y$ is considered equal to the second effect, that is, the unknown number of dollars earned by 14 men in 12 da., the proportion is $\begin{matrix} 4 (\text{men}) \\ 7 (\text{da.}) \end{matrix}$ : 24 (dollars) $= \begin{matrix} 14 (\text{men}) \\ 12 (\text{da.}) \end{matrix}$ : $y$ (dollars). From this, $y \times 4 \times 7 = 24 \times 14 \times 12$, or $28y = 4{,}032$, or $y = \$144$.

EXAMPLE 2.—If 12 men in 35 da. build a wall 140 rd. long, 6 ft. high, how many men can, in 40 da., build a wall of the same thickness 144 rd. long, 5 ft. high?

SOLUTION.—Here, the causes are the men and the number of days worked and the effects are the length and height of wall built by them. It is to be noted that the thickness of the wall is not considered as it is the same for each set of men. If $y$ is made equal to the unknown number of men, $\begin{matrix} 12 (\text{men}) \\ 35 (\text{da.}) \end{matrix}$ : $\begin{matrix} 140 (\text{rd.}) \\ 6 (\text{ft.}) \end{matrix} = \begin{matrix} y (\text{men}) \\ 40 (\text{da.}) \end{matrix}$ : $\begin{matrix} 144 (\text{rd.}) \\ 5 (\text{ft.}) \end{matrix}$. From this, $12 \times 35 \times 144 \times 5 = 140 \times 6 \times y \times 40$, or $33{,}600y = 302{,}400$, or $y = 9$.

## PERCENTAGE

*Percentage* is a process of computation in which the basis of comparison is a hundred.

*Per cent.* means *by*, or *on, the hundred.* 6 per cent. (also written 6%, or .06) of a quantity means 6 of every hundred in the quantity.

The *base* is the amount upon which the percentage is computed. In the case of money at interest, the base is known as the *principal.*

The *rate*, or *rate per cent.*, is the number of hundredths of the base that are to be taken. In monetary transactions, the rate is commonly called *interest.*

The *percentage* is the sum obtained by multiplying the base (or principal) by the rate. In finance, the percentage is always known as the *interest.*

The *amount* is the sum of the base and percentage or, what is the same thing, the sum of the principal and interest.

**To Find the Percentage, Having the Rate and the Base.**—Multiply the base by the rate expressed in hundredths. Thus 6% of 1,930 is found as follows: $1{,}930 \times .06 = 115.80$.

**To Find the Amount, Having the Base and the Rate.**—Multiply the base by 1 plus the rate. Thus, the amount of \$1,930 for 1 yr. at 6% is $\$1{,}930 \times 1.06 = \$2{,}045.80$.

**To Find the Base, Having the Rate and the Percentage.**—Divide the percentage by the rate. Thus, if the rate is 6% and the percentage is 115.80, the base $= 115.80 \div .06 = 1{,}930$.

**To Find the Rate, Having the Percentage and the Base.**—Divide the percentage by the base. Thus, if the percentage is 115.80 and the base 1,930, the rate equals $115.80 \div 1{,}930 = .06$, or 6%.

**To Find the Rate, Having the Amount and Base.**—Subtract the base from the amount; this will give the percentage. Divide the percentage by the base to find the rate. Thus, if the amount is \$2,045.80 and the base is \$1,930, the

percentage (or interest) is $2,045.80 - $1,930 = $115.80. The rate is then $115.80 ÷ 1,930 = .06, or 6%.

**Interest.**—Interest is money paid for the use of money, and may be likened to rent paid for the use of a house by a tenant to his landlord. Interest is figured as a certain per cent. of the money lent; 6% is the prevailing rate in the United States.

In banks interest is generally figured on the basis of there being 360 da., or 12 mo. of 30 da. each, in the year. The following are short rules for calculating 6% interest when 360 da. are taken as 1 yr.:

**Rule I.**—*Multiply the principal by the number of days and divide by 6,000.*

**Rule II.**—*Multiply the principal by the number of months and divide by 200.*

At 6% a year, the interest on $1 for 1 mo. is $\frac{1}{2}$%.

A *note* is a written promise to pay a certain sum of money at a certain time and at a certain rate of interest and, usually, at a certain place. The amount of money to be paid is the principal and is often called the *face* of the note. The *discount* is the interest on the money for the given time and at the given rate, and is so called because it is deducted (or discounted) in advance. The *proceeds* is the net amount received; that is, it is the face of the note less the discount (or interest) paid in advance.

Banks charge interest, as already explained, on the basis of there being 360 da. in the year, and for the exact number of days elapsed. Notes are commonly made for 1, 2, or 3 mo., or for 30, 60, or 90 da. Thus, if on June 15 three sums are borrowed for 1, 2, and 3 mo. time, the notes will be due on the 15th day of July, August, and September, respectively. But interest will not be charged for $\frac{1}{12}$, $\frac{1}{6}$, and $\frac{1}{4}$ yr. in the individual cases, but for 30, 61, and 92 da., and these days are $\frac{30}{360}$, $\frac{61}{360}$, and $\frac{92}{360}$ yr., respectively. On the other hand, should three other sums of money be borrowed on the same day for 30, 60, and 90 da., the notes will fall due on July 15, August 14, and September 13, and interest would be charged for the 30, 60, and 90 da.

**EXAMPLE 1.**—What is the date of payment, discount, and proceeds of a 90-da. note, for $150, dated July 27?

**SOLUTION.**—The date of payment will be 90 da. from July 27, or on October 25, as there are 31 da. each in the months of July and August. The discount will be the interest for 90 da. at 6%, which by rule I is $(150 \times 90) ÷ 6,000 = $2.25. The proceeds will be $150 - $2.25 = $147.75.

**EXAMPLE 2.**—What is the date of payment, discount, and proceeds of a 3-mo. note for $150, dated July 27?

**SOLUTION.**—The date of payment is 3 mo. from July 27, or October 27. As the number of days between these dates is 92, by rule I the discount will be $(150 \times 92) ÷ 6,000 = $2.30. The proceeds will be $150 - $2.30 = $147.70.

**Trade Discount.**—A discount is an abatement from the price of an article for some consideration, frequently the payment of cash upon the receipt of the goods or material purchased. Discounts are generally expressed as a certain per cent. of the purchase price; therefore, the *net*, or real, *cost* of an article is found by multiplying the first cost by 1.00 minus the discount. Thus, if a carload of corn is billed at $438, with a discount of 5% for cash, the price for immediate payment will be $438 \times (1.00 - .05) = 438 \times .95 = $416.10.

Discounts are frequently compound or continuous; that is, there are two or more discounts upon the price of an article. Thus, a discount may be quoted as "ten, ten, and five." This does not mean that the total discount is the sum of the three single discounts, or 25%; each discount and the resultant net price are figured separately. In the case in queston, if the first cost of the article was $100, the first net cost will be $100 \times (1.00 - .10 = .90) = $90; the second net cost will be $90 \times (1.00 - .10 = .90) = $81; and the third net, or final cost will be $81 \times (1.00 - .05 = .95) = $76.95. The total discount is, therefore, $100.00 - $76.95 = $23.05, or 23.05% and not 25%.

## RECIPROCALS

The *reciprocal* of a number is unity, or 1, divided by the number. Thus, the reciprocal of 5 is $1 ÷ 5 = .2$. Reciprocals are always expressed decimally. The reciprocal of a whole number is entirely decimal, while the reciprocal of a number less than unity is either a whole number or a whole number followed by a decimal. Thus, the reciprocal of .5 is $1 ÷ .5 = 2$, and the reciprocal of .6 is $1 ÷ .6 = 1.6666+$. Reciprocals are used to avoid the labor of division. Thus, the operation represented by $100 ÷ 621$ may be performed in the ordinary way by long division, or 100 may be multiplied by the reciprocal of 621. Reciprocals of numbers from 1 to 1,000 are given in connection with the table of powers,

etc., near the end of this volume. From this table, the reciprocal of 621 is found to be .001610306, and $100 \div 621 = 100 \times .001610306 = .1610306$.

Reciprocals of numbers that are multiples or submultiples of those in the table may be obtained directly therefrom by shifting the decimal point. Thus, the reciprocal of 62,100 is $\frac{1}{100}$ of the reciprocal of 621, or .00001610306. The reciprocal of 6.21 is 100 times the reciprocal of 621, or .1613036, and the reciprocal of .0621 is 10,000 times that of 621, or 16.10306.

Reciprocals of numbers intermediate between those in the table may be found therefrom by interpolation. Thus, the reciprocal of 621.25 is .001609579, and by shifting the decimal point the reciprocal of 6.2125 is .16096579.

## ARITHMETICAL PROGRESSION

Quantities are said to be in *arithmetical progression* when they increase or decrease by a common difference. The following is an increasing series in arithmetical progression: 1, 3, 5, 7, 9, 11, 13; if the figures are read backwards, 13, 11, 9, etc., it becomes a decreasing series. In the first series, the *first term* is 1; the *last term* 13; the *number of terms* 7; the *common difference* 2; and the *sum* of the terms 49. In any arithmetical progression,

Let
$$f = \text{first term};$$
$$l = \text{last, or } n\text{th term};$$
$$d = \text{common difference};$$
$$n = \text{number of terms};$$
$$s = \text{their sum}.$$

$$l = f + (n-1)d \qquad (1)$$

$$l = \frac{2s}{n} - f \qquad (2)$$

$$l = \frac{s}{n} + \frac{(n-1)d}{2} \qquad (3)$$

$$l = -\frac{d}{2} \pm \sqrt{2ds + \left(f - \frac{d}{2}\right)^2} \qquad (4)$$

$$f = \frac{2s}{n} - l \qquad (5)$$

$$f = l \pm (n-1)d \qquad (6)$$

$$f = \frac{s}{n} - \frac{(n-1)d}{2} \qquad (7)$$

$$f = \frac{d}{2} \pm \sqrt{\left(l + \frac{d}{2}\right)^2 - 2ds} \qquad (8)$$

$$n = \frac{l-f}{d} + 1 \qquad (9)$$

$$n = \frac{2s}{f+l} \qquad (10)$$

$$n = \frac{d - 2f \pm \sqrt{(2f-d)^2 + 8ds}}{2d} \qquad (11)$$

$$n = \frac{2l + d \mp \sqrt{(2l+d)^2 - 8ds}}{2d} \qquad (12)$$

$$d = \frac{l-f}{n-1} \qquad (13)$$

$$d = \frac{2(s-fn)}{n(n-1)} \qquad (14)$$

$$d = \frac{(l-f)(l+f)}{2s - (l+f)} \qquad (15)$$

$$d = \frac{2(nl-s)}{n(n-1)} \qquad (16)$$

$$s = \frac{n}{2}(f+l) \qquad (17)$$

$$s = \frac{n}{2}[2f + (n-1)d] \qquad (18)$$

$$s = \frac{l+f}{2} + \frac{(l+f)(l-f)}{2d} \qquad (19)$$

$$s = \frac{n}{2}[2l - (n-1)d] \qquad (20)$$

EXAMPLE 1.—During the last month of the year, the mules at a certain mine used 40 bales of hay. The consumption was 2 bales less than this during November, and similarly less for each month until the first of the year. What was the consumption of hay during January, and how many bales were used during the year?

SOLUTION.—Here $n = 12$ (mo.), $d = 2$ (bales), and $l = 40$ (bales during December). It is required to find $f$ and $s$. To find $f$, substituting the various values in formula 6 gives $f = 40 - (12-1) \times 2 = 40 - 22 = 18 =$ number of bales used in January. To find $s$, substituting in formula 20 gives $s = \frac{12}{2} \times [2 \times 40 - (12-1) \times 2] = 6 \times (80-22) = 6 \times 58 = 348$ bales during the year. It will be noted that $f$ has been found in the first part of the solution and it may be used to find $s$ in formula 17 which is more simple than formula 20.

EXAMPLE 2.—A contractor agrees to put down a bore hole for \$1 a ft. for the first 100 ft.; \$3 a ft. for the second 100 ft.; and \$2 a ft. additional for each successive 100 ft. Upon completion of the work he was paid \$6,400. How deep was the hole and what was the cost per foot of the last 100 ft.?

SOLUTION.—Here $f = 100$ (dollars), $s = \$6,400$, and $d = 200$ (dollars increase in cost per 100 ft.). Using formula 11,

$$n = \frac{200 - (2 \times 100) + \sqrt{[(2 \times 100) - 200]^2 + (8 \times 200 \times 6,400)}}{2 \times 200}$$

$$= \frac{200 - 200 + \sqrt{(200 - 200)^2 + 10,240,000}}{400} = \frac{0 + \sqrt{0^2 + 10,240,000}}{400}$$

$$= \frac{\sqrt{10,240,000}}{400} = \frac{3,200}{400} = 8$$

That is, there are 8 sections each 100 ft. deep, or the total depth of the hole is $8 \times 100 = 800$ ft. By using the value of $n$, just found, the last term be determined by means of the simple formula 1. By substitution, the last term $= 100 + (8-1) \times 200 = 100 + 1,400 = 1,500$. That is, the last 100 ft. cost $1,500, or $15 a ft.

## GEOMETRICAL PROGRESSION

A series of quantities, in which each is derived from that which precedes it, by multiplication by a constant quantity, is called a *geometrical progression*. If the multiplier is a whole number, the progression is styled *increasing*; if it is a fraction, the progression is styled *decreasing*. The series 1, 2, 4, 8, 16, 32 has 2 for a multiplier, and is an increasing progression. The series 32, 16, 8, 4, 2, 1, $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{8}$, $\frac{1}{16}$, $\frac{1}{32}$ has $\frac{1}{2}$ for a multiplier, and is a decreasing progression.

The common multiplier in a geometrical progression is called the *common ratio*; or, briefly, the *ratio*.

Let  $f = $ first term;
$l = $ last term, whose number from $f$ is $n$;
$n = $ number of terms;
$r = $ ratio;
$s = $ sum of terms.

$$l = fr^{n-1} \quad (1)$$

$$l = \frac{f + s(r-1)}{r} \quad (2) \qquad n = \frac{\log\left[\frac{s(r-1)}{f} + 1\right]}{\log r} \quad (6)$$

$$f = \frac{l}{r^{n-1}} \quad (3) \qquad \log r = \frac{\log \frac{l}{f}}{n-1} \quad (7)$$

$$f = s - r(s-l) \quad (4) \qquad r = \frac{s-f}{s-l} \quad (8)$$

$$n = \frac{\log \frac{l}{f}}{\log r} + 1 \quad (5) \qquad s = \frac{f(r^n - 1)}{r - 1} \quad (9)$$

$$s = \frac{lr - f}{r - 1} \quad (10)$$

EXAMPLE 1.—How much will it cost to sink a shaft 1,500 ft. deep at the rate of $\frac{1}{16}$c. for the first 50 ft.; $\frac{1}{8}$c. for the second 50 ft.; $\frac{1}{4}$c. for the third 50 ft.; and so on at the same rate?

SOLUTION.—In this case, $f = \frac{1}{16}$; $n = 30$; and $r = 2$. Substituting in formula 1, $l = \frac{1}{16} \times (2^{29}) = 33,554,432$, and from formula 10

$$s = \frac{33,554,432 \times 2 - \frac{1}{16}}{2 - 1} = \$671,088.63\frac{15}{16}$$

EXAMPLE 2.—At the end of a certain period a mine had produced 126,000 T. of coal. The production for the first 6 mo. was 2,000 T., which was doubled each 6 mo. How long had the mine been in operation?

SOLUTION.—In this case, $s = 126,000$; $f = 2,000$; and $r = 2$. Using formula 6 to find $n$. $n = \dfrac{\log\left[\dfrac{126,000 \times (2-1)}{2,000} + 1\right]}{\log 2} = \dfrac{\log 64}{\log 2} = \dfrac{1.80618}{.30103} = 6$. Hence, the mine had been in operation for six periods of 6 mo. each, or for 3 yr.

## INVOLUTION

*Involution* is the process of finding any power of a number. The power of a number is the product arising from multiplying the number by itself as many times as is indicated by another number known as the exponent. Thus, $4^2$ is read *four squared*, or *four to the second power*, and is equal to $4 \times 4 = 16$. Similarly $5^3$ is read *five cubed*, or *five to the third power*, and is equal to $5 \times 5 \times 5 = 125$. Likewise, $2^5$ is read *two to the fifth power*, or *the fifth power of two*, and is equal to $2 \times 2 \times 2 \times 2 \times 2 = 32$. The figures 2, 3, and 5, written to the right and above the numbers are the *exponents*.

## FIRST NINE POWERS OF FIRST NINE NUMBERS

| Number | Square | Cube | Fourth Power | Fifth Power | Sixth Power | Seventh Power | Eighth Power | Ninth Power |
|---|---|---|---|---|---|---|---|---|
| 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 |
| 2 | 4 | 8 | 16 | 32 | 64 | 128 | 256 | 512 |
| 3 | 9 | 27 | 81 | 243 | 729 | 2,187 | 6,561 | 19,683 |
| 4 | 16 | 64 | 256 | 1,024 | 4,096 | 16,384 | 65,536 | 262,144 |
| 5 | 25 | 125 | 625 | 3,125 | 15,625 | 78,125 | 390,625 | 1,953,125 |
| 6 | 36 | 216 | 1,296 | 7,776 | 46,656 | 279,936 | 1,679,616 | 10,077,696 |
| 7 | 49 | 343 | 2,401 | 16,807 | 117,649 | 823,543 | 5,764,801 | 40,353,607 |
| 8 | 64 | 512 | 4,096 | 32,768 | 262,144 | 2,097,152 | 16,777,216 | 134,217,728 |
| 9 | 81 | 729 | 6,561 | 59,049 | 531,441 | 4,782,969 | 43,046,721 | 387,420,489 |

The power of a number may be obtained by multiplying together any two or more lower powers, the sum of whose exponents is equal to the exponent of the required power. Thus, if $n =$ any number, $n^9 = n^4 \times n^5 = n \times n^2 \times n^6 = n^2 \times n^3 \times n^4$, etc. Similarly, $n^7 = n^2 \times n^2 \times n^3 = n^2 \times n^5$, etc.

A table of squares and cubes is given at the end of this volume. The powers of numbers not in the table may be found by interpolation with sufficient accuracy for most purposes. Logarithms afford a rapid method of determining powers.

## EVOLUTION

The *root* of a number is one of the equal factors of a number. The number of equal factors in any number is indicated by a number known as the *index* of the root. This index, which is written to the left and a little above the sign √, shows how many factors compose the number, or how many times the root must be multiplied by itself to produce the number.

**To Find the Square Root of a Number:**

**Rule.—I.** *Separate the given number into periods of two figures each, beginning at the units place.*

**II.** *Find the greatest number whose square is contained in the period on the left; this will be the first figure in the root. Subtract the square of this figure from the period on the left, and to the remainder annex the next period to form a dividend.*

**III.** *Divide this dividend, omitting the figure on the right, by double the part of the root already found, and annex the quotient to that part, and also to the divisor; then, multiply the divisor thus completed, by the figure of the root last obtained, and subtract the product from the dividend.*

**IV.** *Add the root last found to the last trial divisor to form a new trial divisor. Divide the dividend by this new trial divisor and the quotient will be the next figure of the root, which quotient is to be annexed to the trial divisor to form a new complete divisor. Multiply this last complete divisor by the figure of the root last obtained and subtract from the dividend.*

**V.** *Bring down the next period to form a new dividend and continue as before until all the periods have been used.*

**VI.** *If it is desired to carry the root farther, annex periods of two ciphers each, and proceed as before.*

Example.—Find the square root: (a) of 874.225; (b) of .00874225.

Solution.—

(a)
```
 2      8'7 4.2 2'5 0 ( 2 9.5 6 7 +
 2      4
 4 9    4 7 4
   9    4 4 1
 5 8 5    3 3 2 2
     5    2 9 2 5
 5 9 0 6    3 9 7 5 0
       6    3 5 4 3 6
 5 9 1 2 7    4 3 1 4 0 0
              4 1 3 8 8 9
```

(b)
```
 0      .0 0'8 7'4 2'2 5 (.0 9 3 5
 0      0
 9      8 7
 9      8 1
 1 8 3    6 4 2
     3    5 4 9
 1 8 6 5    9 3 2 5
            9 3 2 5
```

**To Find the Cube Root of a Number:**

**Rule.—I.** *Separate the given number into periods of three figures, each beginning at the units place.*

**II.** *Find the greatest number whose cube is contained in the period on the left; this will be the first figure in the root. Subtract the cube of this figure from the period on the left, and to the remainder annex the next period to form a dividend.*

**III.** *Divide this dividend by the partial divisor, which is three times the square of the root already found considered as tens; the quotient is the second figure of the root.*

**IV.** *To the partial divisor add 3 times the product of the second figure of the root by the first, considered as tens, also the square of the second figure; the result will be the complete divisor.*

**V.** *Multiply the complete divisor by the second figure of the root, and subtract the product from the dividend.*

**VI.** *If there are more periods to be brought down, proceed as before, using the part of the root already found, the same as the first figure in the previous process.*

**VII.** *If it is desired to carry the root farther, annex periods of three ciphers each, and proceed as above.*

**EXAMPLE.**—Find the cube root of 12,813,904.

SOLUTION.—

```
                                          1 2'8 1 3'9 0 4 ( 2 3 4
                                  2³       8
First partial divisor, 3×20²   =  1 2 0 0      4 8 1 3
               3×20×3 =            1 8 0
                   3² =               9
First complete divisor         =  1 3 8 9      4 1 6 7
Second partial divisor, 3×23²=1 5 8 7 0 0      6 4 5 9 0 4
               3×230×4 =        2 7 6 0
                   4² =           1 6
Second complete divisor    = 1 6 1 4 7 6       6 4 5 9 0 4
```

A table of squares and cubes is given at the end of this volume by means of which square roots and cube roots may be readily extracted. The roots of numbers whose powers are within the limits of the table, 1,000,000 for squares and 1,000,000,000 for cubes, may be obtained directly, by finding in the proper column, the number whose root is to be extracted and in the column headed Number the root will be found. Thus, if it is desired to extract the cube root of 825,293,672, the number will be found in the column headed Cube, and on the same line in the column headed Number are the figures 938, which is the cube root of the required number.

Often, by shifting and replacing the decimal point, the roots of numbers not in the table may conveniently be found. The decimal point must be shifted the number of figures there are in a period, two in the case of squares and three in that of cubes. Thus, if it is desired to extract the cube root of 14.706125, the decimal point may be shifted either three or six figures (one or two periods) to the right and the cube root of 14,706.125 or of 14,706,125 extracted. After the root is extracted, the decimal point must be restored. In the case just given, by shifting the decimal point six places, or two periods, the cube root of 14,706,125 is found to be 245. As there is but one period before the decimal point in the number, there can be but one figure before the decimal point in the root; hence, the root is 2.45. Similarly, in extracting the cube root of .000000100544625 the decimal point and the six ciphers (two periods) may be dropped and the cube root of 100,544,625 extracted. This root is found to be 465. As there are two periods (of three ciphers each) after the decimal point in the number, there must be two ciphers (one for each period) after the decimal point in the root. Hence, the cube root of .000000100544625 is .00465.

The square or cube roots of numbers not in the table may be found, approximately, by interpolation. When finding the square root of 874.225, the decimal point may be shifted one period, or two figures, to the right, and the square root of 87'422.50 extracted. This is found to be between the squares of 295 and 296. The interpolation is made as follows:

| Number | Root | | Number | Root |
|---|---|---|---|---|
| 87,616 | = 296² | | 87,422.50 | = ? |
| 87,025 | = 295² | | 87,025.00 | = 295² |
| 591 | = first difference | | 397.50 | = second difference |

Then, second difference ÷ first difference = 397.50 ÷ 591 = .656. This is to be added to 295 and the square root of 87,422.50 is found to be 295.656. As the decimal point has been shifted *one period* to the right it must now be shifted *one figure* to the left, and the square root of 874.225 is 29.5656. As the true root, 29.5673, is within .0017 of the root found by interpolating in the table, this method is accurate enough for all practical purposes.

**Finding the Fourth and the Fifth Root of a Number.**—*Fourth roots* may be found by taking the square root of the square root, that is, by extracting the square root twice.

*Fifth roots* are rarely required, and when needed, occur in formulas involving coefficients of friction ($k$, in problems relating to ventilation, etc.) whose values are uncertain within 50% or more. Under such circumstances, it is apparent that even a very large percentage of error in the fifth root is allowable. In the vast majority of cases, no error of importance will be introduced by using for the true root the nearest value thereto, taken directly from the table.

**TABLE OF FIFTH POWERS**

| No. | Power | No. | Power | No. | Power | No. | Power |
|---|---|---|---|---|---|---|---|
| 1.0 | 1.00000 | 3.3 | 391.35393 | 5.6 | 5,507.31776 | 7.9 | 30,770.56399 |
| 1.1 | 1.61051 | 3.4 | 454.35424 | 5.7 | 6,016.92057 | 8.0 | 32,768.00000 |
| 1.2 | 2.48832 | 3.5 | 525.21875 | 5.8 | 6,563.56768 | 8.1 | 34,867.84401 |
| 1.3 | 3.71293 | 3.6 | 604.66176 | 5.9 | 7,149.24299 | 8.2 | 37,073.98432 |
| 1.4 | 5.37824 | 3.7 | 693.43957 | 6.0 | 7,776.00000 | 8.3 | 39,390.40643 |
| 1.5 | 7.59375 | 3.8 | 792.35168 | 6.1 | 8,445.96301 | 8.4 | 41,821.19424 |
| 1.6 | 10.48576 | 3.9 | 902.24199 | 6.2 | 9,161.32832 | 8.5 | 44,370.53125 |
| 1.7 | 14.19857 | 4.0 | 1,024.00000 | 6.3 | 9,924.36543 | 8.6 | 47,042.70176 |
| 1.8 | 18.89568 | 4.1 | 1,158.56201 | 6.4 | 10,737.41824 | 8.7 | 49,842.09207 |
| 1.9 | 24.76099 | 4.2 | 1,306.91232 | 6.5 | 11,602.90625 | 8.8 | 52,773.19168 |
| 2.0 | 32.00000 | 4.3 | 1,470.08443 | 6.6 | 12,523.32576 | 8.9 | 55,840.59449 |
| 2.1 | 40.84101 | 4.4 | 1,649.16224 | 6.7 | 13,501.25107 | 9.0 | 59,049.00000 |
| 2.2 | 51.53632 | 4.5 | 1,845.28125 | 6.8 | 14,539.33568 | 9.1 | 62,403.21451 |
| 2.3 | 64.36343 | 4.6 | 2,059.62976 | 6.9 | 15,640.31349 | 9.2 | 65,908.15232 |
| 2.4 | 79.62624 | 4.7 | 2,293.45007 | 7.0 | 16,807.00000 | 9.3 | 69,568.83693 |
| 2.5 | 97.65625 | 4.8 | 2,548.03968 | 7.1 | 18,042.29351 | 9.4 | 73,390.40224 |
| 2.6 | 118.81376 | 4.9 | 2,824.75249 | 7.2 | 19,349.17632 | 9.5 | 77,378.09375 |
| 2.7 | 143.48907 | 5.0 | 3,125.00000 | 7.3 | 20,730.71593 | 9.6 | 81,537.26976 |
| 2.8 | 172.10368 | 5.1 | 3,450.25251 | 7.4 | 22,190.06624 | 9.7 | 85,873.40257 |
| 2.9 | 205.11149 | 5.2 | 3,802.04032 | 7.5 | 23,730.46875 | 9.8 | 90,392.07968 |
| 3.0 | 243.00000 | 5.3 | 4,181.95493 | 7.6 | 25,355.25376 | 9.9 | 95,099.00499 |
| 3.1 | 286.29151 | 5.4 | 4,591.65024 | 7.7 | 27,067.84157 | 10.0 | 100,000.00000 |
| 3.2 | 335.54432 | 5.5 | 5,032.84375 | 7.8 | 28,871.74368 | | |

This table may be used in the same way as the table of squares and cubes, to find the fifth roots of intermediate values. It must be remembered that the periods are composed of five figures and that there must be one figure in the root for each such period in the number.

EXAMPLE.—Find the fifth root of 3,827,963,000.

SOLUTION.—By pointing off and inserting a decimal point, the fifth root of 38,279.63 is to be extracted. This is seen to lie between 8.2 and 8.3 and an interpolation, which may be made mentally, shows it to be about midway between these or is 8.25. By restoring the decimal point, the fifth root of the given number is found to be 82.5. As the root, by seven-place logarithms, is found to be 82.5265, this simple approximation is accurate enough for use in those formulas in which fifth roots occur. Should greater accuracy be demanded it is possible to interpolate as follows:

| *Number* | *Root* | *Number* | *Root* |
|---|---|---|---|
| 39,390.40463 | = 8.3⁵ | 38,279.63000 | = ? |
| 37,073.98432 | = 8.2⁵ | 37,073.98432 | = 8.2⁵ |
| 2,316.42031 | = first difference | 1,205.64568 | = second difference |

Second difference ÷ first difference = 1,205.64568 ÷ 2,316.42031 = .5205, which is to be annexed to 8.2, making the root 8.25205. By restoring the decimal point the fifth root of 3,827,963,000 is 82.5205.

**Simple Method of Extracting Roots.**—A simple method of extracting roots where tables are not available and the rules have been forgotten, is based upon Sir Isaac Newton's Method of Approximating the Roots of Higher Equations. The method is based on the fact that any number is composed of as many equal factors as are indicated by the index of the root. Thus, the fifth root is one of the five equal factors of the number and the cube root is one of the three equal factors, and similarly.

If the number whose root is required is placed equal to $n$ in the case of the cube root, it may be considered that $a \times b \times c = n$. When these factors are equal, that is, when $a = b = c$, the cube root is found. From the given equation, $a \times b \times c = n$, $c = \dfrac{n}{a \times b}$. If $a$ is made equal to $b$, and a value is assumed for them as near the cube root as possible, the average of the values of $a$, $b$, and $c$, will be nearer the true root than either $a$ or $b$. This value of $c$ is known as the first approximation, and may be placed equal to $a$ and $b$ to find a new value for $c$, the average of the three values being the second approximation. These approximations may be carried indefinitely, but with a little practice it will be found that the first approximation answers all practical purposes.

EXAMPLE 1.—Find the cube root of 987,654,321.

SOLUTION.—Pointing off and inserting a decimal point, it is necessary to extract the cube root of 987.654321. If a table of cubes is not available, one should be prepared. The number will be found between $729 = 9^3$ and $1,000 = 10^3$; that is, the cube root of the number is between 9 and 10. In this case $a \times b \times c = 987.654321$, and when $a = b = c$, the root is found. An interpolation between the cube roots of 729 and 1,000 shows that the cube root of the number is about 9.92. Making $a = b = 9.92$ and substituting gives $9.92 \times 9.92 \times c = 987.654321$, from which $c = 10.036$. The mean of these values is $(9.92 + 9.92 + 10.036) \div 3 = 9.95867$. This is the first approximate root, which may be placed equal to $a$ and $b$ to find a second approximate root. In the case of the first root, by restoring the decimal point, the cube root of 987,654,321 is found to be 995.867, which is identical with that extracted by means of seven-place logarithms. Such coincidence is unusual, but indicates that by carefully selecting the trial factors, a first approximation answers for all but abstract problems.

EXAMPLE 2.—Find the fifth root of 3,827,963,000.

SOLUTION.—Pointing off and placing a decimal point between the periods gives $a \times b \times c \times d \times e = 38,279.63$. From a table of powers, the fifth root of this number is found to lie between 8 and 9, and an interpolation shows it to be about 8.21. Then $8.21 \times 8.21 \times 8.21 \times 8.21 \times e = 38,279.63$. From this $e = 8.425$, and the mean of the five factors is 8.253. Restoring the decimal point shows that the first approximate fifth root of 3,827,963,000 is 82.53. This may be used for a second approximation, giving 82.5261, but the first should answer any purpose. This method may be compared with that based on the use of tables.

# LOGARITHMS

## EXPONENTS

By the use of *logarithms*, the processes of multiplication, division, involution, and evolution are greatly shortened, and some operations may be performed that would be impossible without them. Ordinary logarithms cannot be applied to addition and subtraction. A *logarithm* is the exponent of the power to which a fixed number, called the *base*, must be raised to produce a given number.

Although any positive number except 1 can be used as a base and a table of logarithms calculated, but two numbers have ever been employed. For all arithmetical operations (except addition and subtraction) the logarithms used are called the *Briggs*, or *common*, *logarithms*, and the base used is 10. In abstract mathematical analysis, the logarithms used are variously called *hyperbolic*, *Napierian*, or *natural* logarithms, and the base is 2.718281828+. The common logarithm of any number may be converted into a Napierian logarithm by multiplying the common logarithm by 2.30258509+, which is usually expressed as 2.3026, and sometimes as 2.3. Only the common system of logarithms will be considered here.

As in the common system the base is 10, all numbers are to be regarded as powers of 10; therefore, as $10^1 = 10$, $10^2 = 100$, $10^3 = 1,000$, etc., the logarithms (exponents) of 10, 100, 1,000, etc., are 1, 2, 3, etc., respectively. Similarly,

as $10^{-1} = \frac{1}{10} = .1$, $10^{-2} = \frac{1}{100} = .01$, $10^{-3} = \frac{1}{1000} = .001$, etc., the logarithms (exponents) of .1, .01, .001, etc., are $-1$, $-2$, $-3$, etc., respectively.

From the foregoing, it is seen that while the logarithms of exact powers of 10 and of decimals like, .1, .01, .001, etc., are whole numbers, the logarithms of all other numbers are wholly or in part fractional, the fractional part being expressed decimally. Thus, to produce 20, 10 must have an exponent of approximately 1.30103, or $10^{1.30103} = 20$, very nearly, the degree of exactness depending on the number of decimal places used. Hence, log $20 = 1.30103$. A logarithm, therefore, usually consists of two parts; a whole number, called the *characteristic*, and a fraction, called the *mantissa*. While mantissas are always to be regarded as positive, characteristics may be either positive or negative. From the foregoing, it is apparent that the characteristics of the logarithms of all numbers less than unity are negative, while for numbers greater than unity, they are positive. Negative characteristics are expressed by the sign, $-$, placed above the figures; thus, log $.20 = \bar{1}.30103$.

**Rule for Characteristics.**—*The characteristic of the logarithm of a number equal to or greater than unity is 1 less than the number of digits in the number. In the case of numbers less than unity, the characteristic is determined by the position, with respect to the decimal point, of the first digit in the number. If the first digit is found in the tenths column, the characteristic is $\bar{1}$; if in the hundredths column, it is $\bar{2}$; and similarly; or the characteristic is 1 more than the number of ciphers following the decimal point.*

| | | | |
|---|---|---|---|
| Log .0005 | $= \bar{4}.69897$ | Log 5 | $= .69897$ |
| Log .005 | $= \bar{3}.69897$ | Log 50 | $= 1.69897$ |
| Log .05 | $= \bar{2}.69897$ | Log 500 | $= 2.69897$ |
| Log .5 | $= \bar{1}.69897$ | Log 5,000 | $= 3.69897$ |
| | | Log 50,000 | $= 4.69897$ |

## FINDING THE LOGARITHM OF A NUMBER

A table of logarithms, containing the mantissas of the logarithms from 1 to 9,999 to five places of decimals, is given at the end of this volume. The mantissas of logarithms of larger numbers can be found by interpolation. This table depends on the principle that all numbers having the same figures in the same order have the same mantissa, without regard to the position of the decimal point, which affects the characteristic only. This is apparent from an inspection of the table giving the logarithm of 5 and its multiples and submultiples by 10.

The logarithm of a number having not more than four figures may be found by the following rule:

**Rule.**—*Find the first three significant figures of the number whose logarithm is desired, in the left-hand column; find the fourth figure in the column at the top (or bottom) of the page; and in the column under (or above) this figure, and opposite the first three figures previously found, will be the mantissa or decimal part of the logarithm. The characteristic being found, as previously described, write it at the left of the mantissa, and the resulting expression will be the logarithm of the required number.*

**EXAMPLE.**—Find the logarithm: (*a*) of 6; (*b*) of 48; (*c*) of 300; (*d*) of 3,717; (*e*) of .006195.

**SOLUTION.**—(*a*) The mantissa of the logarithm of 6 is the same as the mantissa of the logarithm of 600. The mantissa is found in the column headed L. 0 and opposite 600 in the column headed N. (number). The first two figures in the mantissa are not repeated for each number, but are found (in this instance) opposite the number 589, and are 77. The last three numbers are found opposite the figures 600. The complete mantissa is 77815. The characteristic is positive and since the number (6) consists of but one digit, the characteristic is $1 - 1 = 0$, therefore, log $6 = .77815$.

(*b*) The mantissa of the logarithm of 48 is the same as the mantissa of the logarithm of 480. As before, this is found in the column headed L. 0 and opposite 480 in the column headed N. The mantissa is 68124. As the number is composed of two figures, the characteristic is $2 - 1 = 1$, therefore, log $48 = 1.68124$.

(*c*) The mantissa of 300 may be taken directly from the table, being found in the column headed L. 0 opposite 300 in the column headed N. The mantissa is 47712. The characteristic, as the number is composed of three figures, is $3 - 1 = 2$, therefore, log $300 = 2.47712$.

(*d*) First find 371 in the column headed N. On the same horizontal line and in the column headed 7, the last three figures of the mantissa are found

to be *019. This star means that the first two figures of the mantissa are to be found below the horizontal line in which 019 is found and not above, and are 57 and not 56. The entire mantissa becomes 57019. As the number is composed of four figures, the characteristic is $4 - 1 = 3$; therefore, log 3,717 = 3.57019.

(e)  The mantissa of 6,195 is found opposite 619. The first two figures, 79, are found in the column headed L. 0, and the last three, 204, in the column headed 5. The entire mantissa is 79204. As the first digit in the number is found in the third decimal place, the characteristic is $\overline{3}$, therefore, log .006195 = 3.79204.

The logarithm of a number consisting of five or more figures may be found by the following rule:

**Rule.—I.** *If the number consists of more than five figures and the sixth figure is 5 or greater, increase the fifth figure by 1 and write ciphers in place of the sixth and remaining figures.*

**II.** *Find the mantissa corresponding to the logarithm of the first four figures, and subtract this mantissa from the next greater mantissa in the table; the remainder is the difference.*

**III.** *Find in the secondary table, headed P. P., a column headed by the same number as that just found for the difference, and in this column, opposite the number corresponding to the fifth figure (or fifth figure increased by 1) of the given number (this figure is always situated at the left of the dividing line of the column), will be found the P. P. (proportional part) for that number. The P. P. thus found is to be added to the mantissa found in II, as in the preceding examples, and the result is the mantissa of the logarithm of the given number, as nearly as may be found with five-place tables.*

To take out the logarithm of a number consisting of more than four figures, it is inexpedient to use more than five figures of the number when using five-place logarithms (the logarithms given at the end of this volume are five-place). Hence, if the number consists of more than five figures and the sixth figure is less than 5, replace all figures after the fifth with ciphers; if the sixth figure is 5 or greater, increase the fifth figure by 1 and replace the remaining figures with ciphers. Thus, if the number is 31,415,926, find the logarithm of 31,416,000; if 31,415,426, find the logarithm of 31,415,000.

EXAMPLE.—Find log 31,416.

SOLUTION.—Find the mantissa of the logarithm of the first four figures, as already explained. This is, in the present case, .49707. Now, subtract the number in the column headed 1, opposite 314 (the first three figures of the given number), from the next greater consecutive number, in this case 721, in the column headed 2. $721 - 707 = 14$; this number is called the *difference*. At the extreme right of the page will be found a secondary table headed P. P., and at the top of one of these columns, in this table, in bold-face type, will be found the difference. It will be noticed that each column is divided into two parts by a vertical line, and that the figures on the left of this line run in sequence from 1 to 9. Considering the difference column headed 14, opposite the number 6 (6 is the last or fifth figure of the number whose logarithm we are taking out) is the number 8.4, which, added to the mantissa just found, disregarding the decimal point in the mantissa, gives $49,707 + 8.4 = 49,715.4$. Now, as 4 is less than 5, it is rejected, giving for the complete mantissa .49715. As the characteristic of the logarithm of 31,416 is $5 - 1 = 4$, log 31,416 = 4.49715.

## TO FIND A NUMBER WHOSE LOGARITHM IS GIVEN

**Rule.—I.** *Consider the mantissa first. Glance along the different columns of the table that are headed 0, until the first two figures of the mantissa are found. Then, glance down the same column until the third figure is found (or 1 less than the third figure). Having found the first three figures, glance to the right along the row in which they are situated until the last three figures of the mantissa are found. Then, the number that heads the column in which the last three figures of the mantissa are found is the fourth figure of the required number, and the first three figures lie in the column headed N, and in the same row in which lie the last three figures of the mantissa.*

**II.** *If the mantissa cannot be found in the table, find the mantissa that is nearest to, but less than, the given mantissa, and which call the next less mantissa. Subtract the next less mantissa from the next greater mantissa in the table to obtain the difference. Also, subtract the next less mantissa from the mantissa of the given logarithm, and call the remainder the P. P. Looking in the secondary table headed P. P. for the column headed by the difference just found, find the number opposite the P. P. just found (or the P. P. corresponding most nearly to that just*

*found); this number is the fifth figure of the required number; the fourth figure will be found at the top of the column containing the next less mantissa, and the first three figures in the column headed N and in the same row that contains the next less mantissa.*

**III.** *Having found the figures of the number as directed, locate the decimal point by the rules for the characteristic, annexing ciphers to bring the number up to the required number of figures if the characteristic is greater than 1.*

EXAMPLE.—Find the number corresponding: (*a*) to the logarithm 3.56867; (*b*) to the logarithm $\bar{2}.05753$.

SOLUTION.—(*a*) The first two figures of the mantissa are 56; glancing down the column, the third figure, 8 (in connection with 820 )is found opposite 370 in the N column. Glancing to the right along the row containing 820, the last three figures of the mantissa, 867, are found in the column headed 4; hence, the fourth figure of the required number is 4, and the first three figures are 370, making the figures of the required number 3,704. As the characteristic is 3, there must be $3+1=4$ figures to the left of the decimal point. Hence, the number is 3,704.

(*b*) The mantissa 05753 is not found in the table. The next less mantissa is found in the column headed 1, opposite the figures 114 in the column headed N; hence, the first four figures are 1,141. The mantissa of log 1141 $=05729$, and of log 1142 $=05707$. The difference is 38. The P. P. (proportional part) is the given logarithm—the lesser tabular logarithm, or 05753 $-05729=24$. Under the head of 38 in the P. P. section, 24 is found between 22.8 (opposite 6) and 26.6 (opposite 7). As 24 is nearer the smaller number, the fifth figure of the number is 6, and the entire number is 11,416. As the characteristic is $\bar{2}$, the number is a decimal and there is $2-1=1$ cipher after the decimal point; hence, the number is .011416.

## MULTIPLICATION BY LOGARITHMS

The principle on which the process of multiplication by means of logarithms is based is that log $ab=$ log $a+$ log $b$. To multiply two or more numbers by using logarithms apply the following rule:

**Rule.**—*Add the logarithms of the several numbers, and the sum will be the logarithm of the product. Find the number corresponding to this logarithm, and the result will be the number sought.*

EXAMPLE 1.—Multiply 4.38, 5.217, and 83 together.

SOLUTION.—    Log  4.38 = .64147
             Log 5.217 = .71742
             Log   83 = 1.91908

Adding,                3.27797 = log (4.38×5.217×83)

Number corresponding to 3.27797 is 1,896.6. Hence, $4.38×5.217×83 =1,896.6$,nearly. By actual multiplication, the product is 1,896.58818, showing that the result obtained by using logarithms was correct to five figures.

When adding logarithms, the algebraic sum is always to be found. Hence, if some of the numbers multiplied together are wholly decimal, the algebraic sum of the characteristics will be the characteristic of the product. It must be remembered that the mantissas are always positive.

EXAMPLE 2.—Multiply 49.82, .00243, 17, and .97 together.

SOLUTION.—

             Log  49.82 = 1.69740
             Log .00243 = $\bar{3}$.38561
             Log     17 = 1.23045
             Log    .97 = $\bar{1}$.98677

Adding,                0.30023 = log (49.82×.00243×17×.97)

Number corresponding to .30023 is 1.9963. Hence, $49.82×.00243×17 ×.97=1.9963$.

In this case the sum of the mantissas was 2.30023. The integral 2 added to the positive characteristics makes their sum $=2+1+1=4$; sum of negative characteristics $=\bar{3}+\bar{1}=\bar{4}$, whence $4+(-4)=0$. If, instead of 17, the number had been .17 in this example, the logarithm of .17 would have been $\bar{1}$.23045, and the sum of the logarithm would have been $\bar{2}$.30023; the product would then have been .019963.

## DIVISION BY LOGARITHMS

The principle upon which the process of division by means of logarithms is based is that $\log \frac{a}{b} = \log a - \log b$.

**Rule I.**—*Subtract the logarithm of the divisor from the logarithm of the dividend, and the result will be the logarithm of the quotient.*

EXAMPLE 1.—Divide 6,784.2 by 27.42.

SOLUTION.—
Log 6,784.2 = 3.83150
Log    27.42 = 1.43807

$difference = \overline{2.39343} = \log (6,784.2 \div 27.42)$

Number corresponding to 2.39343 is 247.42. Hence, $6,784.2 \div 27.42 = 247.42$.

When subtracting logarithms, their algebraic difference is to be found. The operation may sometimes be confusing, because the mantissa is always positive, and the characteristic may be either positive or negative.

**Rule II.**—*When the logarithm to be subtracted is greater than the logarithm from which it is to be taken, or when negative characteristics appear, subtract the mantissa first, and then the characteristic, by changing its sign and adding.*

EXAMPLE 2.—Divide 274.2 by 6,784.2.

SOLUTION.—
Log    274.2 = 2.43807
Log 6,784.2 = 3.83150

$\overline{2}.60657$

First subtracting the mantissa .83150 gives .60657 for the mantissa of the quotient. In subtracting, 1 had to be taken from the characteristic of the minuend, leaving a characteristic of 1. Subtract the characteristic 3 from this, by changing its sign and adding $1 - 3 = \overline{2}$, the characteristic of the quotient. The number corresponding to $\overline{2}.60657$ is .040417. Hence, $274.2 \div 6,784.2 = .040417$.

EXAMPLE 3.—Divide .067842 by .002742.

SOLUTION.—
Log .067842 = $\overline{2}$.83150
Log .002742 = $\overline{3}$.43807

$difference = 1.39343$

As $.83150 - .43807 = .39343$ and $-2 + 3 = 1$, number corresponding to 1.39343 is 24.742. Hence, $.067842 \div .002742 = 24.742$.

The only case that is likely to cause trouble in subtracting is that in which the logarithm of the minuend has a negative characteristic, or none at all, and a mantissa less than the mantissa of the subtrahend. For example, let it be required to subtract the logarithm 3.74036 from the logarithm $\overline{3}$.55145. The logarithm $\overline{3}$.55145 is equivalent to $-3 + .55145$. Now, if both $+1$ and $-1$ are added to this logarithm, it will not change its value. Hence, $\overline{3}.55145 = -3 - 1 + 1 + .55145 = \overline{4} + 1.55145$. Therefore, $\overline{3}.55145 - 3.74036 =$

$\overline{4} + 1.55145$
$3 + .74036$

$difference = \overline{7} + .81109 = \overline{7}.81109$

Had the characteristic of the logarithm been 0 instead of $\overline{3}$, the process would have been exactly the same. Thus, $.55145 = \overline{1} + 1.55145$; hence,

$\overline{1} + 1.55145$
$3 + .74036$

$difference = \overline{4} + .81109 = \overline{4}.81109$

EXAMPLE 4.—Divide .02742 by 67.842.

SOLUTION.—
Log .02742 = $\overline{2}$.43807 = $\overline{3}$ + 1.43807
Log 67.842 = 1.83150 = 1 + .83150

$difference = \overline{4} + .60657 = \overline{4}.60657$

Number corresponding to $\overline{4}$.60657 is .00040417. Hence, $.02742 \div 67.842 = .00040417$.

EXAMPLE 5.—What is the reciprocal of 3.1416?

SOLUTION.—Reciprocal of $3.1416 = \frac{1}{3.1416}$, and $\log \frac{1}{3.1416} = \log 1 - \log 3.1416 = 0 - .49715$. Since $0 = -1 + 1$,

$\overline{1} + 1.00000$
.49715

$difference = \overline{1} + .50285 = \overline{1}.50285$

Number whose logarithm is $\overline{1}$.50285 is .31831.

## INVOLUTION BY LOGARITHMS

The process of involution by means of logarithms is based on the principle that log $a^n = n$ log $a$.

**Rule I.**—*Multiply the logarithm of the number by the exponent that denotes the power to which the number is to be raised; the result will be the logarithm of the required power.*

EXAMPLE 1.—What is: (a) the square of 7.92? (b) the cube of 94.7? (c) the 1.6 power of 512, that is, the value of $512^{1.6}$?

SOLUTION.—(a) Log 7.92 = .89873; exponent of power = 2. Hence, .89873 × 2 = 1.79746 = log $7.92^2$. Number corresponding to 1.79746 is 62.727. Hence, $7.92^2 = 62.727$, nearly.

(b) Log 94.7 = 1.97635; 1.97635 × 3 = 5.92905 = log $94.7^3$. Number corresponding to 5.92905 is 849,280, nearly. Hence, $94.7^3 = 849,280$, nearly.

(c) Log $512^{1.6} = 1.6 \times$ log 512 = 1.6 × 2.70927 = 4.334832, or 4.33483 (when using five-place logarithms) = log 21,619. Hence, $512^{1.6} = 21,619$, nearly.

**Rule II.**—*If the number is wholly decimal, so that the characteristic is negative, multiply the two parts of the logarithm separately by the exponent of the number. If, after multiplying the mantissa, the product has a characteristic, add it, algebraically, to the negative characteristic multiplied by the exponent, and the result will be the negative characteristic of the required power.*

EXAMPLE 1.—Raise .0751 to the fourth power.

SOLUTION.—Log $.0751^4 = 4 \times$ log .0751 = 4 × 2.87564. Multiplying the parts separately, $4 \times \bar{2} = \bar{8}$ and 4 × .87564 = 3.50256. Adding the 3 and 8, 3 + (−8) = −5; therefore, log $.0751^4 = \bar{5}.50256$. Number corresponding to this is .00003181. Hence, $.0751^4 = .00003181$.

A decimal may be raised to a power whose exponent contains a decimal as follows:

EXAMPLE 2.—Raise .8 to the 1.21 power.

SOLUTION.—Log $.8^{1.21} = 1.21 \times \bar{1}.90309$. There are several ways of performing the multiplication.

*First Method.*—Adding the characteristic and mantissa algebraically, the result is −.09691. Multiplying this by 1.21 gives −.1172611, or −.11726, when using five-place logarithms. To obtain a positive mantissa, add +1 and −1; whence, log $.8^{1.21} = −1 + 1 − .11726 = \bar{1}.88274$.

*Second Method.*—Multiplying the characteristic and mantissa separately gives −1.21 + 1.09274. Adding characteristic and mantissa algebraically, gives −.11726; then, adding +1 and −1, log $.8^{1.21} = \bar{1}.88274$.

*Third Method.*—Multiplying the characteristic and mantissa separately gives −1.21 + 1.09274. Adding the decimal part of the characteristic to the mantissa gives −1 + (−.21 + 1.09274) = $\bar{1}.88274$ = log $.8^{1.21}$. The number corresponding to the logarithm $\bar{1}.88274$ = .76338.

Any one of these methods may be used, but the first or the third is recommended. The third saves figures but requires the exercise of more caution than does the first method. Below will be found the entire work of multiplication for both $.8^{1.21}$ and $.8^{.21}$.

| $\bar{1}.90309$ | $\bar{1}.90309$ |
|---|---|
| 1.21 | .21 |
| 90309 | 90309 |
| 180618 | 180618 |
| 90309 | +1.1896489 |
| 1.0927389 | −1 −.21 |
| −1.21 | $\bar{1}.9796489$, or $\bar{1}.97965$ |
| $\bar{1}.8827389$, or $\bar{1}.88274$ | |

In the second case, the negative decimal obtained by multiplying −1 and .21 was greater than the positive decimal obtained by multiplying .90309 and .21; hence, +1 and −1 were added, as shown.

## EVOLUTION BY LOGARITHMS

The process of evolution by logarithms is based on the principle that log $\sqrt[n]{a} = \dfrac{\log a}{n}$.

**Rule.**—*Divide the logarithm of the number by the index of the root; the result will be the logarithm of the root.*

EXAMPLE.—Extract: (a) the square root of 77,851; (b) the cube root of 698,970; (c) the 2.4 root of 8,964,300.

SOLUTION.—(a) Log 77,851 = 4.89127; index of root is 2; hence, log $\sqrt{77,851}$ = 4.89127 ÷ 2 = 2.44564; number corresponding to this is 279.02. Hence, $\sqrt{77,851}$ = 279.02, nearly.

(b) Log $\sqrt[3]{698,970}$ = 5.84446 ÷ 3 = 1.94815 = log 88.746; or, $\sqrt[3]{698,970}$ = 88.746.

(c) Log $\sqrt[2.4]{8,946,300}$ = 6.95251 ÷ 2.4 = 2.89688 = log 788.64; or, $\sqrt[2.4]{8,964,300}$ = 788.64, nearly.

If it is required to extract a root of a number wholly decimal, and the negative characteristic will not exactly contain the index of the root, without a remainder, the following rule may be used:

**Rule.**—*Separate the two parts of the logarithm; add as many units (or parts of a unit) to the negative characteristic as will make it exactly contain the index of the root. Add the same number to the mantissa, and divide both parts by the index. The result will be the characteristic and mantissa of the root.*

EXAMPLE 1.—Extract the cube root of .0003181.

SOLUTION.—Log $\sqrt[3]{.0003181}$ = $\dfrac{\log .0003181}{3}$ = $\dfrac{\overline{4}.50256}{3}$.

$$(\overline{4}+\overline{2}=\overline{6}) + (2 + .50256 = 2.50256)$$
$$(\overline{6} \div 3 = \overline{2}) + (2.50256 \div 3 = .83419)$$

or, log $\sqrt[3]{.0003181}$ = $\overline{2}.83419$ = log .068263

Hence, $\sqrt[3]{.0003181}$ = .068263

EXAMPLE 2.—Find the value of $\sqrt[1.41]{.0003181}$.

SOLUTION.—Log $\sqrt[1.41]{.0003181}$ = $\dfrac{\log. .0003181}{1.41}$ = $\dfrac{\overline{4}.50256}{1.41}$.

If −.23 is added to the characteristic, it will contain 1.41 exactly three times. Hence,

$$[-4 + (-.23) = -4.23] + (.23 + .50256 = .73256)$$
$$(-4.23 \div 1.41 = \overline{3}) + (.73256 \div 1.41 = .51955)$$

or, log $\sqrt[1.41]{.0003181}$ = $\overline{3}.51955$ = log .0033079

Hence, $\sqrt[1.41]{.0003181}$ = .0033079

EXAMPLE 3.—Solve, by logarithms, $\dfrac{497 \times .0181 \times 762}{3,300 \times .6517}$ = ?

SOLUTION.—

| | |
|---|---|
| Log | 497 = 2.69636 |
| Log | .0181 = $\overline{2}$.25768 |
| Log | 762 = 2.88195 |

Log product = 3.83599
Log    3,300 = 3.51851
Log    .6517 = $\overline{1}$.81405

Log product = 3.33256

3.83599 − 3.33256 = .50343 = log 3.1874

Hence, $\dfrac{497 \times .0181 \times 762}{3,300 \times .6517}$ = 3.1874

EXAMPLE 4.—Solve $\sqrt[3]{\dfrac{504,203 \times 507}{1.75 \times 71.4 \times 87}}$ by logarithms.

SOLUTION.—

Log 504,203 = 5.70260
Log     507 = 2.70501

Log product = 8.40761
Log    1.75 = .24304
Log    71.4 = 1.85370
Log     87 = 1.93952

Log product = 4.03626

$\dfrac{8.40761 - 4.03626}{3}$ = 1.45712 = log 28.65

Hence, $\sqrt[3]{\dfrac{504,203 \times 507}{1.75 \times 71.4 \times 87}}$ = 28.65

## SOLUTION OF EQUATIONS BY LOGARITHMS

Logarithms can often be applied to the solution of equations.

**EXAMPLE 1.**—Solve the equation $2.43x^5 = \sqrt[6]{.0648}$.

**SOLUTION.**—Dividing by 2.43, $x^5 = \dfrac{\sqrt[6]{.0648}}{2.43}$. Taking the logs of both numbers,

$5 \log x = \dfrac{\log .0648}{6} - \log 2.43$; $5 \log x = \dfrac{\overline{2}.81158}{6} - .38561 = \overline{1}.80193 - .38561$

$= \overline{1}.41632$. Dividing by 5, $\log x = \overline{1}.88326$, whence $x = .7643$.

**EXAMPLE 2.**—Solve the equation $4.5^x = 8$.

**SOLUTION.**—Taking the logarithms of both numbers, $x \log 4.5 = \log 8$,

whence, $x = \dfrac{\log 8}{\log 4.5} = \dfrac{.90309}{.65321}$. Taking logarithms again, $\log x = \log .90309 - \log$

$.65321 = \overline{1}.95573 - \overline{1}.81505 = .14068$, and $x = 1.3825$.

**REMARKS.**—Logarithms are particularly useful in those cases when the unknown quantity is an exponent, as in the last example, or when the exponent contains a decimal, as in several instances in the examples already given. Such examples can be solved without the use of logarithms, but the process is very long and somewhat involved, and the arithmetical work required is enormous. To solve the example last given without using the logarithmic table and obtain the value of $x$ correct to five figures will require, perhaps, 100 times as many figures as are used in the solution given, and the resulting liability to error will be correspondingly increased; indeed, to confine the work to this number of figures will also require a good knowledge of short-cut methods in multiplication and division, and judgment and skill on the part of the calculator, which can only be acquired by practice and experience.

Formulas containing quantities affected with decimal exponents are generally of an empiric nature; that is, the constants or exponents or both are given such values as will make the results obtained by the formulas agree with those obtained by experiment. Such formulas occur frequently in works treating on thermodynamics, strength of materials, machine design, etc.

---

# GEOMETRY

## PRINCIPLES OF GEOMETRY

1. The sum of all the angles formed on one side of a straight line equals two right angles, or 180°.

2. The sum of all the angles formed around a point equals four right angles, or 360°.

3. When two straight lines intersect each other, the opposite or vertical angles are equal.

4. If two angles have their sides parallel, they are equal.

5. If two triangles have two sides, and the included angle of the one equal to two sides and the included angle of the other, they are equal in all their parts.

6. If two triangles have two angles, and the included side of the one equal to two angles and the included side of the other, they are equal in all their parts.

7. In any triangle, the greater side is opposite the greater angle, and the greater angle is opposite the greater side.

8. The sum of the lengths of any two sides of a triangle is greater than the length of the third side.

9. In an isosceles triangle, the angles opposite the equal sides are equal.

10. In any triangle, the sum of the three angles is equal to two right angles, or 180°.

11. If two angles of a triangle are given, the third may be found by subtracting their sum from two right angles, or 180°.

12. A triangle must have at least two acute angles, and can have but one obtuse or one right angle.

13. In any triangle, a perpendicular let fall from the apex to the base is shorter than either of the two other sides.

14. If a triangle is equilateral, it is equiangular, and vice versa.

15. If a straight line from the vertex of an isosceles triangle bisects the base, it bisects the vertical angle and is perpendicular to the base.

16. If one side of a triangle is extended, the exterior angle thus formed, is equal to the sum of the two interior and opposite angles.

17. If two triangles are mutually equiangular, they are similar and their corresponding sides are proportional.

18. Triangles that have an angle in each equal, are to one another as the products of the sides including those equal angles.

19. Similar triangles are to one another as the squares of their corresponding sides.

20. In a right-angled triangle, the square of the hypotenuse is equal to the sum of the squares of the other two sides.

21. If a triangle is inscribed in a semicircle, one side being a diameter, it is right-angled.

22. In any parallelogram, the opposite sides are equal; the opposite angles are equal; it is bisected by its diagonals into two equal triangles, and its diagonals bisect each other.

23. If the sides of a polygon are produced in regular order, the sum of the exterior angles thus formed is equal to 360°.

24. The sum of the interior angles of a polygon is equal to twice as many right angles as the polygon has sides, less four right angles. For example, the sum of the interior angles of a pentagon is $(2 \times 5) - 4 = 6$ right angles, or 540°; of an octagon, $(2 \times 8) - 4 = 12$ right angles, or 1,080°, etc.

25. The diagonals joining the vertices of a regular polygon intersect at the center of the inscribed and circumscribed circles.

26. The angle at the center subtended by the side of a regular polygon is equal to 360° divided by the number of sides.

27. Plane figures are similar when they are bounded by the same number of similar sides and their correspondingly situated angles are equal each to each.

28. The perimeters of similar polygons are to one another as any two corresponding sides; and their areas are to one another as the squares of those sides.

29. The circle is a polygon of an infinite number of sides.

30. A circle may be described about or inscribed within any regular polygon.

31. Through three points not in the same straight line a circle may be made to pass and but one.

32. The diameter of a circle is greater than any chord.

33. Any radius that is perpendicular to a chord, bisects the chord and the arc subtended by it.

34. Arcs and chords of the same circle are proportional to the angles at the center of the circle subtended by them.

35. Similar arcs are proportional to the radii of their circles.

36. A tangent to a circle meets it at one point only, and is perpendicular to the radius at that point.

37. If from a point without a circle tangents are drawn to touch the circle, there are but two such tangents; they are equal, and they make equal angles with the chord joining the points of tangency.

38. The angle between a tangent and a chord is equal to one-half the angle at the center subtended by the chord.

39. The perimeters of circles are to one another as any two corresponding dimensions, and their areas are to one another as the squares of such dimensions.

40. Only five regular polyhedrons are possible; the tetrahedron with four triangular faces; the cube with six square faces; the octahedron with eight triangular faces; the dodecahedron with twelve pentagonal faces; and the icosahedron with twenty triangular faces.

41. The sum of all the angles of the faces of any polyhedron is equal to four right angles taken as many times as the polyhedron has vertices less two.

42. The center of any regular polyhedron and of its circumscribed and inscribed spheres is at the point of intersection of the diagonals joining its opposite vertices.

43. Solids are similar which are bounded by the same number of similar faces similarly placed, and which have their corresponding polyhedral angles equal.

44. The areas of the surfaces of similar solids are to one another as the squares of their similar dimensions, and the volumes of similar solids are to one another as the cubes of like dimensions.

45. The sphere is a regular polyhedron of an infinite number of sides.

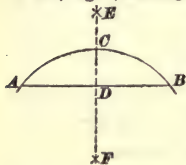
46. A sphere may be described about any regular polyhedron, and its radius is equal to the distance from any vertex to the center; and a sphere may be inscribed within any regular polyhedron, and its radius is equal to the perpendicular distance from the center of any face to the center of the figure.

47. Through four points not in the same plane a spherical surface may be made to pass, and but one.

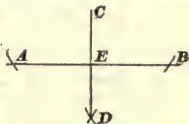
48. From a point without a sphere two tangents may be drawn to a great circle of the sphere, and but two.

49. Through a line without a sphere two tangent planes to the surface of the sphere may be drawn, and but two.

## PROBLEMS IN GEOMETRICAL CONSTRUCTION

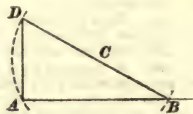
1. **To Bisect a Given Straight Line or the Chord or the Arc of a Circle.** Let *AB*, Fig. 1, be the given line or chord and *ACB* the arc of the circle. With *A* and *B* as centers and with a radius greater than one-half the line *AB* or the arc *ACB*, describe arcs intersecting at *E* and *F*. The line *EF* will bisect the line, chord, or arc.


COROLLARY.—The line *EF* will also be perpendicular to the line *AB* and, when prolonged, will pass through the center of the circle of which *ACB* is the arc.

2. **From a Given Point *C*, Without a Straight Line *AB*, to Draw a Perpendicular to the Line.**—From *C*, Fig. 2, as a center, with a radius greater than the distance from *C* to *AB*, describe an arc cutting the line *AB* at *A* and *B*. From *A* and *B* as centers and with a radius greater than one-half of *AB*, describe arcs intersecting at *D*, and draw the line *CD*.


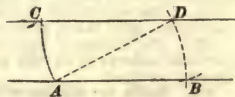
COR.—The line *CD* will bisect that portion of the line included between the points *A* and *B*.

3. **At a Given Point *C* in a Straight Line *AB*, to Erect a Perpendicular to That Line.**—Lay off the points *A* and *B*, Fig. 3, equidistant from *C*, and with *A* and *B* as centers and, with a radius greater than one-half *AB*, describe arcs intersecting at *D*. The line *DC* will be perpendicular to *AB*.

4. **To Erect a Perpendicular at the End *A* of a Given Line *AB*.— *First Method*.**—From any point *C*, Fig. 4, above the line *AB* and with a radius *AC* describe the arc of the circle *AD*, which also cuts the line *AB* at *B*. Connect *B* and *C* and prolong the line to intersect the circle at *D*. The line *AD* will be perpendicular to the line *AB*.


*Second Method*.—From the given point *A*, Fig. 5, set off a distance *AB* equal to three parts by any scale. From *A* and *B* as centers and with radii equal, respectively, to four parts and five parts, draw arcs intersecting at *C*. The line *AC* will be the perpendicular required.

NOTE.—This is one of the methods employed for laying off the coordinates on mine maps.

5. **Through a Given Point *A*, to Draw a Straight Line Parallel to a Given Straight Line *CD*.**—With *A*, Fig. 6, as a center and with a radius greater than the shortest distance from *A* to the line *CD*, describe an indefinite arc *DB*. With *D* as center and with the same radius *DA*, describe the arc *AC*. With *D* as a center and with the radius *AC* describe an arc cutting the arc *DB* at *B*. The line *AB* will be parallel to the line *CD*.


6. **To Draw a Straight Line Parallel to a Given Line and at a Given Distance From It.** *First Method*.—Select any two points *A* and *B*, Fig. 7, on the given line. With these as centers and with radii equal to the distance apart of the lines describe the arcs *C* and *D*. Draw the line *CD* touching the arcs.

FIG. 1

FIG. 2

FIG. 3

FIG. 4

FIG. 5

FIG. 6

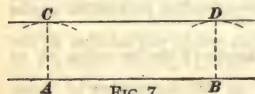


FIG. 7

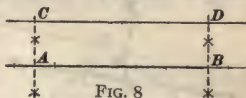
*Second Method.*—At any two selected points *A* and *B*, Fig. 8, in the given line, erect perpendiculars. With *A* and *B* as centers and with a radius equal to the distance apart of the lines, draw arcs of circles cutting the perpendiculars at *C* and *D*. The line *CD* joining these points of intersection will be parallel to the line *AB*.


NOTE.—These methods are employed to lay off the coordinates of mine maps.

FIG. 8

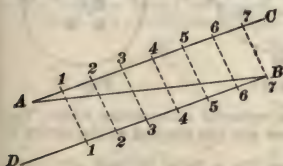
7. **To Divide a Straight Line Into Any Number of Equal Parts.**—Let *AB*, Fig. 9, be a straight line that is to be divided into, say, seven equal parts. Draw the parallel lines *AC* and *BD* making any angle with *AB*, and measure off upon each of them seven equal spaces. Connect the points, *1* and *1*, *2* and *2*, etc., by lines. These lines will divide the line *AB* into seven equal parts.


FIG. 9

Or, but one line *AC* need be drawn. By connecting *7* and *B*, the parallel lines drawn through *6*, *5*, *4*, etc., will divide the line as required.

NOTE.—This method is available for dividing a line into any odd number of parts when no scale of such parts is to be had. Thus, to divide a line, 2⅓ in. long into sevenths, seven ¼ or ½ in., may be laid off along the line *AC*. The operation will, if properly carried out, divide the 2⅓ in. into seven equal parts of .3171 in.

A line may be divided into proportional parts by this method. Thus to divide the line *AB* in the ratio of *3* to *4*. Lay off the distance *A–3* equal to three parts, and the distance *4–7* equal to four parts. The line *3–3* will divide the line *AB* in the required ratio.

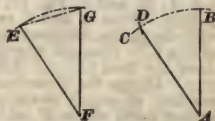
8. **At a Point A on a Given Straight Line** *AB*, **to Make an Angle Equal to a Given Angle** *EFG*.—From *F*, Fig. 10, as a center and with any radius *FG* describe the arc *EG*. From *A* as a center and with the same radius, describe the arc *CB*; then with a radius equal to the chord *EG*, describe an arc from *B* as a center, cutting *CB* at *D*, and draw the line *AD*. The angle *BAD* will be equal to the angle *EFG*.


FIG. 10

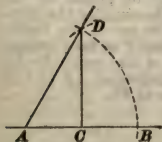
9. **To Draw Angles of 60° and 30°.**—From any point *A*, Fig. 11, on the line *AB* and with any radius *AB* describe the arc *BD*. With *B* as a center and with the same radius *AB*, describe an arc cutting *BD* at *D*. The line *AD* will form an angle *DAB* with *AB* equal to 60°. The perpendicular *DC* to the base will form the angle *ADC* of 30°.

FIG. 11


10. **To Draw an Angle of 45°.**—Lay off any distance *AB*, Fig. 12, and at *B* erect a perpendicular to *AB*. With *B* as a center and with a radius equal to *BA* describe an arc cutting the perpendicular at *C*. The line *AC* will form with the line *AB* an angle *CAB* equal to 45°.

Or, the second method under problem 4 may be used.

FIG. 12

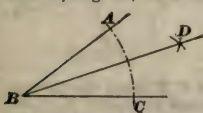
11. **To Bisect an Angle** *ABC*.—With any radius and with *B*, Fig. 13, as a center, describe arcs cutting the sides at *A* and *C*. With *A* and *C* as centers, describe arcs of equal radius intersecting at *D*. The line *BD* is the bisector, and the angle *ABD* = angle *DBC*.


FIG. 13

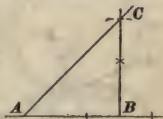
12. **To Bisect an Open Angle** (*Method by* L. L. LOGAN).—Let *AB* and *CD*, Fig. 14, be the sides of an open angle. With any point *O* as a center, describe a circle cutting the sides at *e*, *f*, *g*, and *h*, and with *e* and *f*, and *g* and *h* as centers and any radius, describe arcs intersecting at *k* and *l*, respectively. Draw *Ok* and *Ol* and *mn*. With *p* and *q* as centers, and any radius, describe arcs intersecting at *R* and *S*. The line drawn through *RS* is the required bisector.


**13. To Find the Center of a Given Circumference or Arc.**—*First Method.*
Take any three points $A$, $B$, and $C$, Fig. 15, on the circumference and unite them by lines $AB$ and $BC$. Bisect these chords by the perpendiculars $DO$ and $EO$; their intersection is the center of the circle.

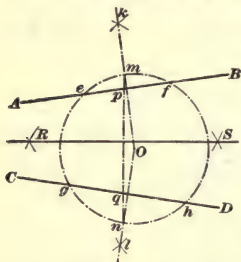
*Second Method.*—Take any three points $A$, $B$, and $C$, Fig. 16, on the circumference as far apart as convenient. With these three points


Fig. 14
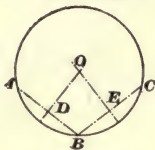

Fig. 15
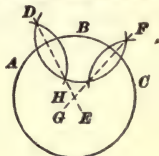

Fig. 16

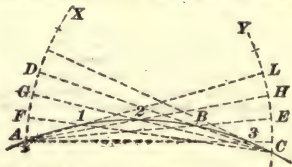
as centers and with the same radius, draw a series of intersecting arcs. The lines $GF$ and $DE$ through these intersections cut one another at the center $H$ of the circle.

NOTE.—This method is employed to describe a circle through any three points not in the same straight line.

**14. To Describe an Arc of a Circle Passing Through Three Given Points When the Center Is Not Available.**
Let $A$, $B$, and $C$, Fig. 17, be the three points. From $A$ and $C$ as centers and with the radius $AC$ describe the arcs $CY$ and $AX$. Through the third point $B$ draw the lines $CD$ and $AE$ cutting the arcs. Divide the distance $AD$ into any number of equal parts and lay off similar parts above $D$ on the arc $AX$.

Fig. 17

Also lay off like parts above and below $E$ on the arc $CY$. Draw lines $CF$, $CG$, etc., and $AH$, $AL$, etc. Their intersection, $1$, and $2$, will be points on the required circle. The curve may be drawn by splines. The smaller the divisions of the arcs, the more points will there be given in the arc of the circle.

**15. To Draw a Tangent to a Circle Through a Given Point $P$ in the Circumference.**—Find the center $C$, Fig. 18, of the circle by any of the methods described and draw the radial line $CD$. At $P$ erect a perpendicular $AB$ to this line $CD$; the perpendicular $AB$ will be tangent to the circle at $P$.


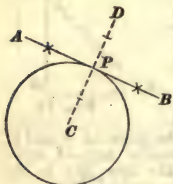


Fig. 18
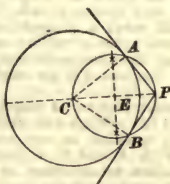

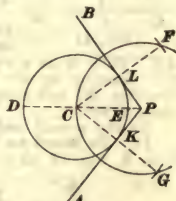

Fig. 19

Fig. 20

**16. To Draw Tangents to a Circle From a Point $P$ Without the Circumference.**—*First Method.*—If the center of the circle is not given find it by any method, and draw the line $PC$, Fig. 19. Bisect this line $PC$ at $E$, and with the radius $EC = PE$, describe a circle cutting the given circle at $A$ and $B$. Connect $A$ and $P$ and $B$ and $P$; the lines $AP$ and $BP$ will be tangent to the circle.

*Second Method.*—As before, let $P$, Fig. 20, be the point. Find the center $C$ of the circle and draw the line $PCD$. With $P$ as a center and with a radius $PC$,

describe the arc FCG. With C as a center and with a radius equal to the diameter DE of the circle, cut this arc at F and G. Draw the lines FC and GC, cutting the circle at L and K. Draw the lines PB and PA through L and K respectively; they will be tangents to the circle.

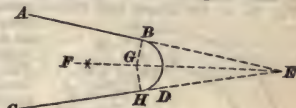
**17. To Draw an Arc of a Circle Tangent to Two Lines Inclined to Each Other, One Point of Tangency B Being Given.**—Produce the given lines, AB and CD, Fig. 21, until they intersect at E. Bisect the angle AEC by the line EF. Draw a perpendicular to the line AB from the point B. Its intersection G with the line EF, the bisector of the angle, is the center of the required arc. The other point of tangency may be found by dropping a perpendicular GH upon the line CD.


FIG. 21

NOTE.—If an intersection cannot be reached, use the method described in problem 12, for bisecting the angle.

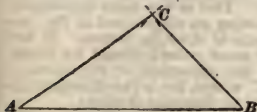
**18. To Construct a Triangle, the Sides Being Given.**—Let AB, Fig. 22, be one of the sides. With A as a center and a radius equal to one of the remaining sides AC, and with B as a center and a radius equal to the third side BC describe the arc AC cutting the arc AC at C. Draw the lines AC and BC; then ABC will be the required triangle.


FIG. 22

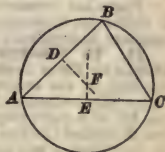
**19. To Describe a Circle About a Triangle.**—Let ABC, Fig. 23, be the triangle. Bisect any two sides as AB and AC at D and E and at these points erect perpendiculars to the sides intersecting at F. With F as a center and with a radius equal to FA = FB = FC, describe the circle ABC.


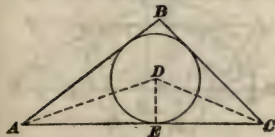
**20. To Inscribe a Circle in a Triangle.**—Let ABC, Fig. 24, be the given triangle. Bisect any two angles, such as A and C, by lines intersecting at D. Drop a perpendicular from D upon any side as DE upon the side AC, and with D as a center and a radius DE, inscribe the circle.


FIG. 23

FIG. 24

**21. To Construct a Hexagon Upon a Given Straight Line.**—Let FE, Fig. 25, be the given line. From its extremities F and E as centers and with the radius FE describe arcs of circles intersecting at G. With a radius GE, draw the circumscribing circle EDCBAF. With the same radius GE = FE set off upon the circumference of this circle the chords ED, DC, CB, and BA. The points so found, when joined, will form the required hexagon.

NOTE.—The side of any hexagon is equal to the radius of its circumscribed circle. As the exterior angles of a hexagon are each equal to 60°, this polygon is readily drawn with a straightedge and a 60°-30° triangle.

FIG. 25

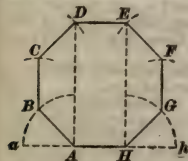
**22. To Describe an Octagon Upon a Given Straight Line.**—Let AH, Fig. 26, be the given line. Produce it in both directions and at A and H erect the perpendiculars AD and HE. Bisect the angles DAa and EHh with the lines AB and HG. With A and H as centers and with a radius AH equal to the length of the given side describe arcs cutting the bisectors at B and G respectively; AB and HG will be sides of the octagon. Draw BC and GF parallel to DA and EH. Make them equal to AH by cutting them (using B and G as centers) with the arcs of a circle whose radius is equal to AH. From C and F as centers and with a radius equal to AH, describe arcs of circles intersecting the perpendiculars at D and E. The lines, CD, DE, and EF, joining the points thus determined, complete the octagon.


FIG. 26

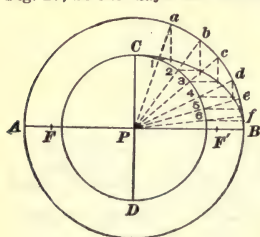
NOTE.—As the exterior angles of an octagon are each 45°, this polygon is readily drawn with a straightedge and a 45° triangle.

**23. To Construct an Ellipse, the Axes Being Given.**—Let $AB$ and $CD$, Fig. 27, be the major and minor axes, respectively, intersecting, bisecting, and

FIG. 27

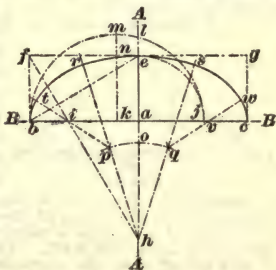
perpendicular to each other at $P$. Using $P$ as a center draw two circles with radii equal, respectively, to one-half the axes, or $PA$ and $PC$. From $P$, draw any number of random lines, as $Pa$, $Pb$, . . . $Pf$ to the circumference of the larger circle and drop perpendiculars from the extremities, $a$, $b$, . . . $f$. From the points of intersection, $1$, $2$, . . . $6$, of the lines $Pa$, $Pb$, etc., with the smaller circle draw lines parallel to the major axis $AB$. The points of intersection of these parallels with the verticals previously drawn will be points on the ellipse. This is the most convenient method of drawing an ellipse and is the one used very largely in drafting rooms. It will be noted that more points should be determined where the direction of the curve is changing rapidly, as at and near $B$, than at $C$ where, for a considerable distance on either side of the minor axis, the change in direction is slight.


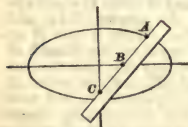
The foci of the ellipse may be found by drawing, with $C$ or $D$ as a center and with $PA = PB$ as a radius, arcs of circles cutting the major axis at $F$ and $F'$.

There are numerous complicated and inaccurate methods of drawing what is called an approximate ellipse, three of which are given, but they do not compare in simplicity with the exact method given.

**24. To Construct an Approximate Ellipse, the Axes Being Given.** *Method by Three Centers.*—Let $a$, Fig. 28, be the center, $bc$ the major, and $ae$ one-half the minor axis of an ellipse.

FIG. 28

Draw the rectangle $bfgc$, and the diagonal line $be$; at a right angle to the line $be$, draw line $fh$ cutting the line $BB$ at $i$. With radius $ae$, and from $a$ as a center, draw the dotted arc $ej$, giving the point $j$ on the line $BB$. From $k$, which is central between $b$ and $j$, draw the semicircle $bmj$, cutting the line $AA$ at $l$. Draw the radius of the semicircle $bmj$, cutting $fg$ at $n$. With radius $mn$, mark on the line $AA$, from $a$ as a center, the point $o$. With radius $ho$, and from center $h$, draw the arc $poq$. With radius $al$, and from $b$ and $c$ as centers, draw arcs cutting the arc $poq$ at the points $p$ and $q$. Draw the lines $hpr$ and $hqs$, and also the lines $pit$ and $qvw$. From $h$ as a center, draw that part of the ellipse lying between $r$ and $s$ with radius $hr$. From $p$ as a center draw that part of the ellipse lying between $r$ and $t$ with the radius $pr$. From $q$, draw the ellipse from $s$ to $w$. With radius $it$, from $i$ as a center, draw the ellipse from $t$ to $b$ with radius $it$, and from $v$ as a center, draw the ellipse from $w$ to $c$, and one-half the ellipse will be drawn. It will be noted that the whole construction has been performed to find the centers $h$, $p$, $q$, $i$, and $v$, and that while $v$ and $i$ may be used to carry the curve around the other side or half of the ellipse, new centers must be provided for $h$, $p$, and $q$; these new centers correspond in position to $h$, $p$, $q$.




NOTE.—This method is the one commonly employed to lay off concrete, or masonry arches, etc.

*Method by Straightedge.*—On a straightedge, lay off $AB$, Fig. 29, equal to one-half the shorter axis and $AC$ equal to one-half the longer axis. Determine points in the ellipse by marking positions of $A$ as the point $B$ is moved along the major axis, at the same time the point $C$ being kept in the minor axis.

FIG. 29

*Method by Cord.*—Lay off the axes and find the foci as described in problem 23. Stick pins at the foci $F$ and $F'$, Fig. 27. To these pins attach a string making its length equal to $FC + CF'$. The point of a

pencil placed inside the string may be made to describe an ellipse, if the string is kept tightly and uniformly stretched while the pencil is in motion.

NOTE.—This is the method commonly employed to lay off an ellipse upon the ground, as when making garden beds, etc.

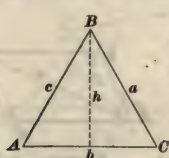
The cord and straightedge methods are theoretically capable of describing a true ellipse. That is, the methods are founded on the mathematical principles governing the ellipse, but it is not generally possible to manipulate either the string or straightedge so that perfect results may be obtained.

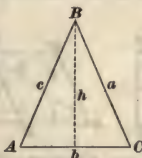
---

# MENSURATION OF SURFACES

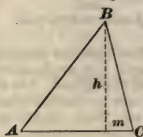
## TRIANGLES

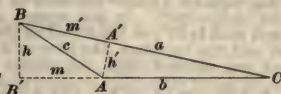
A *triangle* is a plane surface bounded by three straight lines. Some of the different kinds of triangles are shown here.

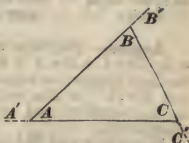




Equilateral          Isosceles          Right-angled





*Acute*                    *Obtuse*


Let  $A$, $B$, $C$ = interior angles
$A'$, $B'$, $C'$ = exterior angles
$b$ = side called base
$A$ = area
$m$ = distance from foot of
$h$ to nearest vertex

$a$, $b$, $c$ = sides opposite angles $A$, $B$, and $C$
$P$ = perimeter
$h$ = perpendicular upon base from vertex of angle opposite

**Angles.**—$A + B + C = 180°$. $A = 180° - (B + C)$, and similarly for $B$ and $C$. $A + A' = 180°$, and similarly for $B + B'$ and $C + C'$. $A' = 180° - A$, and similarly for $B'$ and $C'$. $A' + B' + C' = 360°$. $A' = 360° - (B' + C')$, and similarly for $B'$ and $C'$. $A' = B + C$; $B' = A + C$; $C' = A + B$.

**Perimeter and Sides.**—$P = a + b + c$. In all acute-angled triangles, including equilateral, isosceles, and right-angled triangles, any side $a = \sqrt{b^2 + c^2 - 2bm}$. In an obtuse-angled triangle, the side opposite the obtuse angle $a = \sqrt{b^2 + c^2 + 2bm}$.

**Altitude.**—In any triangle, the *altitude*, or perpendicular distance from the base to the vertex of the opposite angle, is $h = \sqrt{c^2 - m^2}$.

**Area.**—In any triangle, the area is equal to the product of the base by one-half the altitude, or $A = \dfrac{bh}{2}$. Any side may be selected as the base. Thus, in the obtuse-angled triangle, if the base is the side $b$, $A = \dfrac{bh}{2}$; if the base is the side $a$, $A = \dfrac{ah'}{2}$. If the length of the three sides is given, let $p$ = one-half the sum of the three sides, or $p = \dfrac{a + b + c}{2}$, and $A = \sqrt{p(p - a)(p - b)(p - c)}$; that is, *the area is equal to the square root of one-half the sum of the sides multiplied by this one-half sum less each one of the sides, respectively.*

**Special Cases.**—*Equilateral Triangle.*—Angle $A = B = C = 60°$. Side $a = b = c$. Altitude $h = \text{side} \times .866025$. Side $= h \div .866025 = h \times 1.154701$. Side $= \sqrt{\text{area}} \times 1.51967$. Area $= \text{side}^2 \times .443013$. Length of side of square having same area as an equilateral triangle $= \text{side of triangle} \times .658037$. Diameter of circle of same area as an equilateral triangle $= \text{side of triangle} \div 1.34677$. The perpendicular $h$ bisects the angle $B$ and the side $b$; and similarly for the other angles and sides. This triangle is also known as the equiangular or 60° triangle.

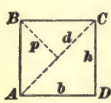
*Isosceles Triangle.*—Angle $A = C$. $B = 90° - A$ or $C$. Side $a = c$. The perpendicular $h$ bisects the angle $B$ and the side $b$.

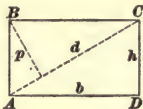
*Right-Angled Triangle.*—Angle $A = 90°$. Angles $B + C = 90°$. Side $a^2 = b^2 + c^2$, and $a = \sqrt{b^2 + c^2}$, $b = \sqrt{a^2 - c^2}$, $c = \sqrt{a^2 - b^2}$.

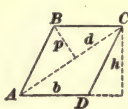
For other properties and methods of solving triangles, see under Trigonometry.

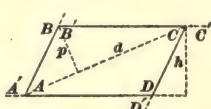
## PARALLELOGRAMS

A *parallelogram* is a plane figure bounded by four straight lines which are parallel, two and two. Some of the different kinds of parallelograms are shown here.



*Square.*—Four
equal sides
and four right
angles


*Rectangle.*—Four
right angles
and opposite
sides equal


*Rhombus.*—Four
equal sides
and
oblique angles


*Rhomboid.*—Four
oblique angles
and
opposite sides equal

**Angles.**—The sum of the exterior angles = the sum of the interior angles $= A + B + C + D = A' + B' + C' + D' = 360°$. In the square and the rectangle, the four angles are equal and each is 90°; in the rhombus and rhomboid, $A = C$ and $B = D$. In the square and the rhombus, the diagonals are perpendicular to one another and bisect one another and the angles at their opposite extremities.

**Perimeter and Sides.**—Let the sides be $a$, $b$, $c$, and $d$, respectively, then the perimeter, $P = a + b + c + d$. In the square and rectangle, any side = area ÷ by an adjacent side. In the rhombus and rhomboid, a side = area ÷ by the altitude $h$. In all four cases, the diagonal $d$ = area ÷ by perpendicular $p$.

**Area.**—In all cases, the area $A = bh = dp$.

**Square.**—Diagonal $d = \text{side} \times 1.41421$. Side = diagonal $\times .707107$. The side of a square equal in area to a given circle = diameter of circle $\times .886277$. The area of the largest square that may be inscribed in a circle $= 2 \times \text{radius of circle}$.[2]

It should be noted that all problems relating to parallelograms, as well as to trapezoids, trapeziums, and regular and irregular polygons, may be solved by resolving these figures into triangles.

## TRAPEZOIDS

A *trapezoid* is a plane figure bounded by four straight lines, only two of which are parallel one to the other. One is shown in the accompanying figure.

**Angles.**—The sum of the interior angles $= 360°$, or $A + B + C + D = A' + B' + C' + D' = 360°$. $A = B'$; $B = A'$; $C = D'$; $D = C'$. $A = 180° - A'$; $B = 180° - B'$; and similarly for $C$ and $D$. $A + B = C' + D'$; $A + C = B' + D'$; $A + D = B' + C'$; $B + C = A' + D'$; and similarly for other combinations of $A$, $B$, $C$, and $D$.

**Perimeter.**—The sides being $a$, $b$, $c$, and $d$, the perimeter $P = a + b + c + d$.

**Diagonal.**—The diagonal $d = 2 \times \text{area} \div (p + p')$.

**Area.**—*Case I.*—Given the two parallel sides $a$ and $c$ and the perpendicular distance between them $h$, $A = \dfrac{h}{2}(a + c)$.

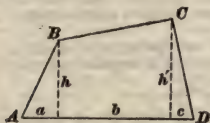
*Case II.*—Given the diagonal $d$ and the perpendiculars upon it $p$ and $p'$.
$$A = \frac{d}{2}(p + p').$$

*Case III.*—Given the two parallel sides $a$ and $c$ and the angles adjacent to one of them, $A$ and $D$, the area,
$$A = \frac{c^2 - a^2}{2(\cot A + \cot B)} = \frac{(c-a)(c+a)\sin A \sin B}{2\sin(A+B)}$$

*Case IV.*—Given all four sides $a$, $b$, $c$, and $d$. Let $c - a = f$, and $\frac{1}{2}(b + d + f) = s$, then area $A = \frac{(a+c)}{f}\sqrt{s(s-d)(s-b)(s-f)}$.

## TRAPEZIUMS

A *trapezium* is a plane figure bounded by four straight lines, no two of which are parallel.



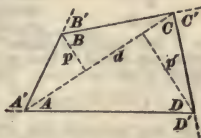


FIG. 1        FIG. 2

**Angles.**—As with trapezoids, the sum of the interior angles = the sum of the exterior angles = 360°. Also, $A = 180° - A'$, and similarly for $B$, $C$, and $D$.

**Perimeter and Diagonal.**—The same relations prevail for the perimeter and the diagonal as for trapezoids.

**Area.**—In the trapezium shown in Fig. 1, $A = \frac{1}{2}[b(h + h') + ah + ch']$.

In the trapezium shown in Fig. 2, $A = \frac{d}{2}(p + p')$.

## POLYGONS

A *polygon* is a plane figure bounded by three or more straight lines. Some of the more common forms are shown in Fig. 1.

*Pentagon*        *Hexagon*        *Heptagon*        *Octagon*

FIG. 1

If all the sides and angles are equal, each to each, the figure is a regular polygon; otherwise it is not. Of the figures previously discussed, the equilateral triangle and the square are regular polygons; the others are irregular.

In any regular polygon, Fig. 2, let the central angle $(AOB = BOC,$ etc.) $= C$; let the interior angle $(ABC = BCD,$ etc.) $= I$; let the exterior angle $(A'AB = B'BC,$ etc.) $= E$. Also let $R = \frac{D}{2} =$ radius of circumscribed circle, and let $r = \frac{d}{2} =$ radius of inscribed circle = apothem. Likewise, let $S =$ length of a side as $AB$, $BC$, etc., and let $N =$ number of sides.

**Central Angle.**—The central angle is equal to the exterior angle and is equal to 360° divided by the number of sides in the polygon, or $C = E = \frac{360°}{N}$. The sum of either the central or the exterior angles of any polygon is 360°.

**Interior Angle.**—The interior angle is equal to 180° minus either the central or the exterior angle, or $I = 180° - C = 180° - E$. The sum of all the interior angles of any polygon is equal to twice as many right angles as the polygon has sides, less four right angles, or $\Sigma I = (2 \times N \times 90°) - 360°$.

FIG. 2

**Diagonals.**—The diagonals $AD$, $BE$, etc., of a regular polygon bisect the interior angles $I$, bisect one another, intersect at the center of the inscribed and circumscribed circles, divide the polygon into as many isosceles triangles as it has sides; also, they are the diameters $D$ of the circumscribed circle.

**Apothems.**—The apothems $LO$, etc., of a regular polygon are perpendicular to the sides. They bisect the sides, the central angles, and one another; divide the fundamental isosceles triangles of the polygon into two equal right angled triangles $BLO + CLO = BOC$; and are the radii $r$ of the inscribed circle.

**Perimeter and Sides.**—The perimeter of any polygon is equal to the sum of the lengths of all its sides. The perimeter of a regular polygon, $P = NS$. Any side, $S = 2\sqrt{R^2 - r^2} = 2R \sin \dfrac{C}{2} = 2r \tan \dfrac{C}{2} = \dfrac{P}{N}$.

**Area.**—In any polygon, the area is equal to the sum of the areas of the triangles into which it is divided by its diagonals. The area of a regular polygon is equal to the area of one of the fundamental triangles, as $AOB$, multiplied by the number of sides. Likewise,

$$A = Nr^2 \tan \frac{C}{2} = \tfrac{1}{2}NR^2 \sin C = \tfrac{1}{2}NSr = \tfrac{1}{2}Pr.$$

The accompanying table gives, for the more important regular polygons, the number of sides; the name; the central angle, which equals the exterior angle; the interior angle; the length of the side, in terms of the radius of both the circumscribed and inscribed circles $R$ and $r$; and the area, in terms of the side $S$ and in terms of the radius of the circumscribed and inscribed circles $R$ and $r$, respectively.

## NAMES AND RELATIONS OF REGULAR POLYGONS

| Number of Sides | Name | Angle | | Side | | Area | | |
|---|---|---|---|---|---|---|---|---|
| | | $C = E$ | $I$ | $R = 1$ | $r = 1$ | $S = 1$ | $R = 1$ | $r = 1$ |
| 3 | Equilateral Triangle | 120° | 60° | 1.73205 | 3.46410 | .43301 | 1.29904 | 5.19615 |
| 4 | Square | 90° | 90° | 1.41421 | 2.00000 | 1.00000 | 2.00000 | 4.00000 |
| 5 | Pentagon | 72° | 108° | 1.17557 | 1.45308 | 1.72048 | 2.37765 | 3.63271 |
| 6 | Hexagon | 60° | 120° | 1.00000 | 1.15470 | 2.59808 | 2.59808 | 3.46608 |
| 7 | Heptagon | 51°25.7' | 128°34.3' | .86776 | .96315 | 3.63391 | 2.73641 | 3.37106 |
| 8 | Octagon | 45° | 135° | .76536 | .82842 | 4.82842 | 2.82840 | 3.31368 |
| 9 | Nonagon | 40° | 140° | .68404 | .72794 | 6.18183 | 2.89253 | 3.27573 |
| 10 | Decagon | 36° | 144° | .61804 | .64984 | 7.69421 | 2.93895 | 3.24921 |
| 11 | Undecagon | 32°43.6' | 147°16.4' | .56346 | .58724 | 9.36581 | 2.97341 | 3.22972 |
| 12 | Dodecagon | 30° | 150° | .51764 | .53590 | 11.19615 | 3.00000 | 3.21538 |

EXAMPLE 1.—What is the length of the side of a triangle inscribed in a circle of 2 in. radius?

SOLUTION.—Here $R = 2$ and the side $S = 2 \times 1.73205 = 3.46410$.

EXAMPLE 2.—What is the length of the side of a pentagon circumscribed about a circle of 4 in. radius?

SOLUTION.—Here $r = 4$ and side $S = 4 \times 1.45308 = 5.81232$ in.

EXAMPLE 3.—What is the area of a hexagon whose side is 2 in. long?

SOLUTION.—Here $S = 2$ and area $= S^2$ or $4 \times 2.59808 = 10.39232$ sq. in.

EXAMPLE 4.—What is the area of a dodecagon that may be inscribed in a circle of 3 in. radius?

SOLUTION.—In this case, $R = 3$ and area $= R^2$ or $9 \times 3.000000 = 27.000000$ sq. in.

EXAMPLE 5.—What is the area of a decagon that may be circumscribed about a circle of 4 in. radius?

SOLUTION.—In this case $r = 4$ and area $= r^2$ or $16 \times 3.24921 = 51.9874$ sq. in.

EXAMPLE 6.—What is the radius of the circle that may be circumscribed about a square whose side is 2 in.?

SOLUTION.—Here $R = 2$ and it is required to find $S$. $S = 2 \div 1.41421 = 1.41421$.

**Area of Irregular Polygons.**—If the figure is bounded by straight lines, to find its area divide it into triangles; the sum of the areas of these will be equal to that of the irregular polygon. This method is commonly used by engineers as a useful check upon the accuracy of the areas obtained by calculation. In many cases the results thus obtained answer every purpose.

If one or more of the boundaries is an irregular line, as would be that of the bank of a river, the area may be found by one of several methods.

*First Method.*—Let $A$ and $E$, Fig. 3, be two corners on the river or on any other irregular boundary. Draw the lines $AF$ and $FE$ to include as much water on the land side as they exclude land on the water side. If the map has been platted by means of coordinates, those of $F$ may be found by measurement, and the area can then be calculated by double latitudes. Or the entire figure may be divided into a series of triangles as shown and the sum of their areas taken as that of the property.

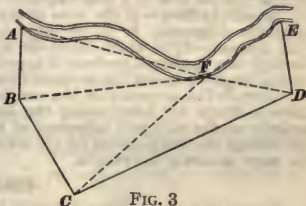

FIG. 3

*Second Method: By Selected Ordinates.*—Draw perpendiculars on $AB$, Fig. 4, from the points of the curve at which its direction changes appreciably, and consider the portion of the curve between two consecutive perpendiculars to be a straight line. The figure is then treated as if divided into a number of trapezoids, whose areas can be computed by the rules already given.

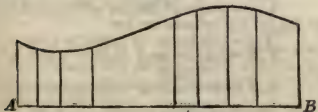

FIG. 4

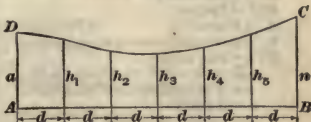

FIG. 5

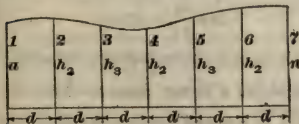
*Third Method: Trapezoidal Rule.*—The ordinates are measured at regular intervals $d$ along the line, as shown in Fig. 5. If the end ordinates are $a$ and $n$ respectively, the area is $A = \left(\dfrac{a+n}{2} + \Sigma h\right)d$ in which $\Sigma h$ is the sum of all the intermediate ordinates.

EXAMPLE.—If the ordinates from the straight line $AB$ to the curved boundary $DC$, are 19, 18, 14, 12, 13, 17, and 23 li., respectively, and are at equal distances of 50 li., what is the area included between the curved boundary and the straight line?

FIG. 6

SOLUTION.—Area $ABCD = \left(\dfrac{19+23}{2} + 18 + 14 + 12 + 13 + 17\right) \times 50 = 4,750$ sq. li.


*Fourth Method: Simpson's Rule.* The base line must be divided into an even number of equal parts, as shown in Fig. 6. The area is then equal to $A = (a + n + 4\Sigma h_2 + 2\Sigma h_3)\dfrac{d}{3}$, in which $a + n$ is the sum of the end ordinates; $4\Sigma h_2$ is four times the sum of all intermediate even-numbered ordinates; and $2\Sigma h_3$ is

twice the sum of all intermediate odd-numbered ordinates.   This rule is more accurate than the trapezoidal rule.

EXAMPLE.—What is the area *ABCD* of the polygon, in the example of the Third Method, according to Simpson's rule?

SOLUTION.—$A = [19+23+4\times(18+12+17)+2\times(14+13)]\times\frac{5.0}{3} = 4,733$ sq. li.

*Fifth Method.*—Prepare two drawings upon paper of the same weight and quality, one of the tract of irregular outline and another of about the same size but of a tract whose area is known, both drawings being to the same scale. Cut each out carefully along the boundary and weigh in a chemist's balance sensitive to milligrams (1 mg. = .015 gr., about).   The area of the irregular figure may be calculated from the proportion:   *The unknown area : the known area = the weight of the drawing of the unknown area : the weight of the drawing of the known area.*

*Sixth Method.*—Draw the figure upon cross-section paper.   If each of the small squares represents a certain area to the scale of the map, the number of whole squares and fractions thereof within the boundary, when multiplied by the relative area of a single square, will give the area of the figure.

*Seventh Method.*—If the area of many irregular figures (such as a series of indicator diagrams) is to be determined, a planimeter should be secured. This instrument, of which there are several types, and which may be secured through any dealer in engineer's supplies, affords the most rapid and accurate means for determining the areas of irregular figures.

NOTE.—The accuracy of the results obtained by the use of these approximate methods for determining the areas of irregular figures depends almost entirely on the skill and judgment of the engineer.   Other things being equal, the smaller the subdivisions (in the method involving ordinates or small squares) the more accurate the results.

## CIRCLES

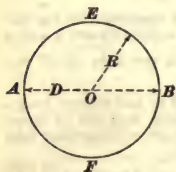
A *circle* is a plane figure bounded by a curved line every point of which is equidistant from an interior point called the *center*.

In the formulas relating to circles the letters have the following meanings: capital letters refer to the larger and lower-case letters to the smaller of two circles concerned in the same formula.

$D, d$ = diameter
$R, r$ = radius
$A, a$ = area
$P, p$ = circumference = perimeter
$H, h$ = rise of arc
$\pi$ = ratio of $P$ to $D$ = 3.1416
$\pi$ = 3.141592653589793238462
$\pi^2$ = 9.86965
$K, k$ = length of chord

$L, l$ = length of arc
$C, c$ = angle at center subtended by chord or arc
$T, t$ = thickness of circular ring
$A, B$ = major and minor axes of ellipse
$a, b$ = semi-major and semi-minor axes
$\sqrt{\pi}$ = 1.772453

$p = \pi d = 3.1416d$
$p = 2\pi r = 6.2832r$
$p = 2\sqrt{\pi A} = 3.5449\sqrt{A}$
$p = \dfrac{2A}{r} = \dfrac{4A}{d}$
$d = \dfrac{p}{\pi} = \dfrac{p}{3.1416} = .3183p$
$d = 2\sqrt{\dfrac{A}{\pi}} = 1.1284\sqrt{A}$

$r = \dfrac{p}{2\pi} = \dfrac{p}{6.2832} = .1592p$
$r = \sqrt{\dfrac{A}{\pi}} = .5642\sqrt{A}$
$A = \dfrac{\pi d^2}{4} = .7854d^2$
$A = \pi r^2 = 3.1416r^2$
$A = \dfrac{pr}{2} = \dfrac{pd}{4}$
$A = \dfrac{p^2}{4\pi} = .0796p^2$


**To Find Diameter of a Circle Equal in Area to a Given Square.**—Multiply one side of the square by 1.12838.

**To Find Radius of a Circle to Circumscribe a Given Square.**—Multiply one side by .7071; or take one-half the diagonal.

**To Find Side of a Square Equal in Area to a Given Circle.**—Multiply the diameter by .88623.

**To Find Side of Greatest Square in a Given Circle.**—Multiply the diameter by .7071.

**To Find Area of Greatest Square in a Given Circle.**—Square the radius and multiply by 2.

### To Find Side of an Equilateral Triangle Equal in Area to a Given Circle.

Multiply the diameter by 1.3468.

Circumferences and areas of circles from 1 to 1,000 units in diameter will be found in connection with the table of squares, cubes, etc. A similar table, but for diameters from $\frac{1}{16}$ to 100, increasing by $\frac{1}{8}$, is also given at the end of the volume. Circumferences and areas of circles whose diameters are not exactly given in the tables, but are within its limits, may be found by interpolation. If the diameters are greater than those given in the table, the circumferences and areas may be found by recalling that the former are proportional to the diameters and the latter to the squares of the diameters. Thus, the circumference and area of a circle 9,380 units in diameter are respectively 10 and 380 times those of a circle 938 units in diameter.

## RINGS

Let $S$ = area and $T$ = thickness of a ring.

$$T = R - r = \frac{D-d}{2} = \frac{P-p}{2\pi} = .159155(P-p)$$

$$S = A - a = \frac{P^2 - p^2}{4\pi} = .079578(P^2 - p^2)$$

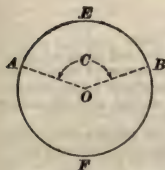
$$S = \pi(R^2 - r^2) = \frac{\pi}{4}(D^2 - d^2) = .785398(D^2 - d^2)$$

## SECTORS

A *sector* is a portion of the surface of a circle included between an arc $AEB$ and two radii $OA$ and $OB$.

$$A = \tfrac{1}{2} lr = \frac{90\,l^2}{\pi C} = \frac{\pi}{360} r^2 C = 28.647823 \frac{l^2}{C} = .00872666 r^2 C$$

$$R = 2\frac{A}{l} = \frac{180}{\pi} \frac{l}{C} = \sqrt{\frac{360}{\pi} \frac{A}{C}} = 57.295646 \frac{l}{C}$$

$$= 10.704732 \sqrt{\frac{A}{C}}$$


The central angle $C$ must be reduced to degrees and decimal parts thereof.

## CIRCULAR SEGMENTS

A *segment* is a portion of the surface of a circle included between an arc $NEM$ and its chord $NM$.

Area segment $NEM$ = area sector $ONEM$ − area triangle $NOM$.

The area of the sector is found from some one of the formulas already given and that of the triangle is found from

$$A' = \frac{k}{2}(r-h) = \tfrac{1}{2} r^2 \sin C = \tfrac{1}{4} k \cot \frac{C}{2} = (k-h)^2 \tan \frac{C}{2}$$

Other formulas are $k = 2\sqrt{h(2r-h)} = 2r \sin \frac{C}{2}$

$$r = \frac{k^2 + 4h^2}{8h} = \frac{k}{2 \sin \frac{C}{2}} \qquad h = r - \sqrt{r^2 - \left(\frac{k}{2}\right)^2} = r\left(1 - \cos \frac{C}{2}\right)$$

$$l = \frac{2\pi}{360} rC = .017453 rC \qquad \sin \frac{C}{2} = \frac{k}{2r}$$

To determine the area of a heading, the upper part of which is the arc of a circle, the width thereof $k$ and the rise of the arc $h$ being given. Find $r$ from the formula $r = \frac{k^2 + 4h^2}{8h}$. Then find $\frac{1}{2}C$ from $\sin \frac{C}{2} = \frac{k}{2r}$. The angle found is $\frac{1}{2}C$ and must be multiplied by 2. $C$ is to be expressed in degrees and decimals thereof. The area of the sector $ONEM$ is now found from the formula $A = .00872664 r^2 C$. The area of the triangle $NMO$ is found from the formula $A' = \frac{k}{2}(r-h)$. Then $A - A'$ = area segment $NEM$, which is to be added to that of the lower rectangular portion of the heading.

## ELLIPSE

If $A$ and $B$ are the axes of an ellipse and $a$ and $b$ are the semi-, or half, axes, the area $A = \pi ab = 3.141593 \ ab = \frac{\pi}{4}AB = .785398AB$.

No simple formula has been developed for finding the perimeter of an ellipse. In terms of the semi-axes, the formula for the perimeter involves the summation of an expanding series of an infinite number of terms:

$$P = \pi(a+b)\left[1 + \frac{1}{4}\left(\frac{(a-b)}{(a+b)}\right)^2 + \frac{1}{64}\left(\frac{(a-b)}{(a+b)}\right)^4 + \frac{1}{256}\left(\frac{(a-b)}{(a+b)}\right)^6 + \text{etc.}\right]$$

In an ellipse whose semi-axes are 4 and 3, the values within the brackets become $1 + .005102041 + .000006507 + .000000033$. It is apparent, then, except in cases involving great accuracy, that the terms beyond the second may be dropped and the formula for the perimeter of an ellipse may be written, $P = \pi(a+b)\left[1 + \frac{1}{4}\left(\frac{(a-b)}{(a+b)}\right)^2\right]$. This, the correct formula, is fully as simple and is, naturally, far more accurate than any of the so-called shorter approximations.

---

# MENSURATION OF SOLIDS

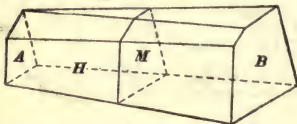
## VALUES USED IN FORMULAS

$V$ = volume of solid
$S$ = area of convex surface
$A$ = area of main base
$a$ = area of second base, or top
$T$ = area of entire surface = $S + A + a$
$h$ = altitude, or perpendicular distance from base to top

$P$ = perimeter of base
$p$ = perimeter of second base or top
$R, r, D, d$ = radius and diameter of main base and of secondary base, respectively; or, radius and diameter of a sphere
$l$ = slant height, or length from base to base measured on surface

## PRISMOID AND PRISMOIDAL FORMULA

A *prismoid* is any solid having two parallel ends or faces of any shape similar or dissimilar, regular or irregular, provided these ends are united by

surfaces, whether plane or curved, on which and through every point of which, a straight line may be drawn from one of the parallel ends to the other. It embraces all polyhedrons, parallelopipeds, prisms, cylinders, cones, pyramids, etc., and even the sphere, which may be regarded as a regular polyhedron of an infinite number of faces.


This is true whether the solids are regular or irregular, right or oblique, and applies to their frustums when cut parallel to the base.

The formula for the volume of a prismoid is

$$V = \frac{H(A + 4M + B)}{6}$$

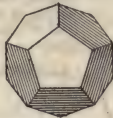
in which $A$ and $B$ = areas of two ends, respectively;
$M$ = area of section taken midway between ends;
$H$ = perpendicular distance between parallel ends.

This is known as the *prismoidal formula*, and from it, by making the proper substitutions for $A$, $M$, and $B$, an equation for the volume of any solid may be deduced, provided this form is included in the definition of a trapezoid. Unless the parallel ends are similar polygons, the mid-section $M$, is not the mean of the sections $A$ and $B$. This formula is extensively used in calculating excavations in railroad work.

## REGULAR POLYHEDRONS

A *polyhedron* is a solid contained within any number of plane sides. A regular polyhedron is one whose bounding planes (faces) are regular polygons of the same shape and area, and whose solid (polyhedral) angles are equal each to each. Unless the sphere is considered a regular polyhedron of an

infinite number of sides, only five regular polyhedrons are possible; these are shown in the accompanying figure.

*Tetrahedron*  *Cube*  *Octahedron*  *Dodecahedron*  *Icosahedron*


## REGULAR POLYHEDRONS WHOSE EDGES ARE UNITY

| Name | Bounding Polygons | Surface | Volume |
|---|---|---|---|
| Tetrahedron | 4 equilateral triangles | 1.732051 | .117851 |
| Hexahedron or cube | 6 squares | 6.000000 | 1.000000 |
| Octahedron | 8 equilateral triangles | 3.464102 | .471405 |
| Dodecahedron | 12 pentagons | 20.645729 | 7.663119 |
| Icosahedron | 20 equilateral triangles | 8.660254 | 2.181695 |

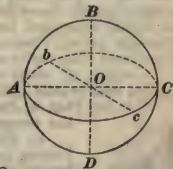
The surface of any regular polyhedron is equal to the number of faces multiplied by the area of a single face. It maybe found from the accompanying table by squaring the length of the edge of a face and multiplying this by the number, in the column headed Surface, opposite the name of the polyhedron. Thus, the surface area of an octahedron whose edge is 2 in. long, is $2^2$, or $4 \times 3.464102 = 14.856408$ sq. in.

The volume of any polyhedron may be obtained by taking the sum of the volumes of the pyramids into which it may be divided. There will be as many pyramids as there are faces in the polyhedron and the bases of these pyramids will be the several faces of the polyhedron. The volumes of the regular polyhedrons may be obtained from the table by multiplying the cube of the length of the edge by the number, in the column headed Volume, opposite the name of the polyhedron concerned. Thus, the volume of a tetrahedron whose edge is 2 in. long, is $2^3$, or $8 \times .117851 = .942808$ cu. in.

## THE SPHERE

The *sphere* may be defined as a regular polyhedron of an infinite number of sides; or as a solid generated by the revolution of a semicircle about its diameter; or as a solid, every point of whose surface is equidistant from a fixed interior point called the center.

A *great circle* of a sphere is the line formed by the intersection of a plane through the center with the surface of the sphere, as $ABCD$ or $AbCc$. Its radius and diameter $r$ and $d$ are the same as those of the sphere; its area $\pi R^2$ may be placed equal to $Z$.



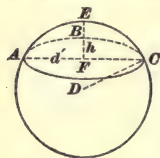
$$R = \sqrt[3]{\frac{3}{4\pi} V} = .62035 \sqrt[3]{V} = \sqrt{\frac{S}{4\pi}} = .2821 \sqrt{S}$$

$$P = \sqrt[3]{6\pi^2 V} = 3.8978 \sqrt[3]{V} = \sqrt{\pi S} = 1.7725 \sqrt{S} = \frac{S}{d} = \pi d = 2\pi r$$

$$S = 4\pi r^2 = 12.5664 r^2 = \pi d^2 = 3.1416 d^2 = \frac{P^2}{\pi} = .3183 P^2 = Pd = 4Z = \frac{6V}{d}$$

$$V = \frac{4}{3}\pi r^3 = 4.1888 r^3 = \frac{\pi}{6} d^3 = .5236 d^3 = \frac{1}{6\pi^2} P^3 = .01689 P^3 = \frac{1}{6} dS = \frac{2}{3} dZ$$

## SPHERICAL SEGMENTS

A *spherical segment* is that portion of a sphere that is included between its surface and a plane cutting it, as *EABCD*. If the plane passes through the center, the sphere is divided into two equal parts, each of which is a hemisphere. Let $EF = h =$ height of segment, and $r'$ and $d'$ be the radius and diameter of the basal plane, and $R$ be the radius of the sphere.


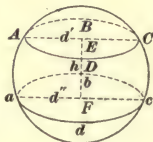
$$S = 2\pi Rh = 6.2832 Rh = \frac{\pi}{4}(d'^2 + 4h^2) = .7854(d'^2 + 4h^2) = Ph$$

To this must be added the area of the base, $\frac{\pi}{4}d'^2$, if the entire surface is required.

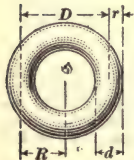
$$V = \pi h^2\left(R - \frac{h}{3}\right) = \pi h^2\left(\frac{d'^2 + 4h^2}{8h} - \frac{h}{3}\right)$$

## SPHERICAL ZONES

A *spherical zone* is that portion of a sphere that is included between two parallel intersecting planes.

Let $d$ be the diameter of the sphere and $d'$ and $d''$ be the diameters $AC$ and $ac$ of the two planes, whose distance apart is $EF = h$.


$$S = PZ = \pi dh = \text{surface of sphere} \times \frac{h}{d}$$

$$V = \frac{\pi}{2} h\left(\frac{d'^2 + d''^2}{4} + \frac{h^2}{3}\right)$$


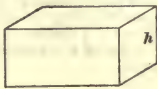
## CYLINDRICAL RINGS

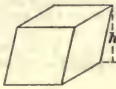
A *cylindrical ring* is produced by bending a cylinder upon itself. Using the notation in the accompanying figure

$$S = 4\pi^2 Rr = 39.4786 Rr = \pi^2 Dd = 9.8697 Dd. \quad V = 2\pi^2 Rr^2$$

$$= 19.7393 Rr^2 = \frac{\pi^2}{4} Dd^2 = 2.4674 Dd^2.$$

## PARALLELOPIPEDS



Cube    Rectangular Prism    Rhombohedron    Rhombic Prism


A *parallelopiped* is a solid bounded by six faces, all of which are parallelograms; opposite faces being parallel. In the cube, there are six equal faces and eight equal solid angles; in the rectangular prism, there are three pairs of equal opposite faces and eight equal solid angles; in the rhombohedron, there are six equal faces and four pairs of equal and diagonally opposite angles; in the rhombic prism, there are three pairs of equal opposite faces and four pairs of equal and diagonally opposite angles.

$S =$ sum of areas of six faces. In the cube and rhombohedron $S = 6A$. In the two prisms (calling the equal faces $A$, $B$, and $C$) $S = 2A + 2B + 2C$.

$V = Ah$; that is, the volume is equal to the area of any face multiplied by the perpendicular distance to the opposite face.

In the cube, $V =$ cube of length of one edge. The diagonal joining opposite vertices $=$ an edge $\times 1.732051$. The radius of the inscribed sphere $=$ the edge $\times .5$. The radius of the circumscribed sphere $=$ one-half the diagonal joining opposite vertices $=$ the edge $\times .866026$.

**Frustum of Prism.**—If a section perpendicular to the edges is a triangle, square, parallelogram, or regular polygon,

$$V = \frac{\text{sum of lengths of edges}}{\text{number of edges}} \times \text{area of right section}$$

## CYLINDERS

A *cylinder of revolution*, which is the common form, is a solid that may be considered to have been generated by the revolution of a parallelogram about one edge.

$$S = 2\pi r h = \pi d h = Ph. \quad T = S + 2 \times \text{area of base} = S + 2A$$

$$A = \pi r^2 = \frac{\pi}{4} d^2 = \frac{1}{2} Pr = \frac{Pd}{4}$$

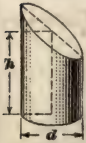
$V$ = area of base × perpendicular height $h$, or $V = Ah = \pi r^2 h$ $= \frac{\pi}{4} d^2 h = \frac{P^2}{4\pi} h = 3.1416 r^2 h = .7854 d^2 h = .0796 P^2 h.$

**Frustum of Cylinder.—**

Let $h$ = one-half sum of greatest and least heights

$$S = Ph = \pi d h$$

$$T = \pi d h + \frac{\pi}{4} d^2 + \text{area of elliptic top.} \quad V = Ah = \frac{\pi}{4} d^2 h$$

**Hollow Cylinders.—**The volumes of hollow cylinders, as the quantity of metal in a pipe, Fig., is found by multiplying the area of the ring made by its cross-section by the length of the cylinder. The area of the cross-section may be determined by the formulas given under Rings.


## THE PYRAMID

A *pyramid*, Fig. 1, is a solid having for its base a plane figure of any number of sides, and for its sides, plane triangles terminating in a common point, called the *apex*.

$S = \frac{1}{2} Pl$, and $T = \frac{1}{2} Pl + A$, in which $P$ is the perimeter of the base, $A$ its area, and $l$ the slant height. Note that $l$, Fig. 1, is not measured on an edge, but from the center of one side of the base to the vertex. These formulas apply to the right regular pyramid in which the base is a regular polygon and the axis is perpendicular thereto. If the base is not a regular polygon and the pyramid is oblique (the axis is inclined to the base), each triangular side has different dimensions. To find $S$, the sum of the areas of the different triangular sides must be taken, to which must be added the area of the irregular base if $T$ is desired.

FIG. 1

The volume of any pyramid is equal to the area of the base multiplied by one-third the altitude, or $V = \frac{1}{3} Ah$.

**Frustum of Regular Pyramid.—**If $A$ and $a$ and $P$ and $p$ are the area and perimeter of the lower and upper bases, respectively, of a frustum of a regular pyramid, Fig. 2,

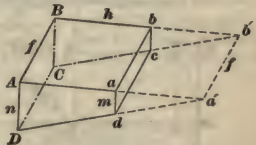
$$S = \frac{1}{2} l (P + p) \text{ and } T = \frac{1}{2} l (P + p) + A + a$$

FIG. 2

If the cutting plane is inclined to the base or the frustum is that of an irregular or oblique pyramid, the surface area $S$ is the sum of the areas of the trapeziums forming the sides, to which must be added the areas of the irregular bases if $T$ is wanted.

The volume of the frustum of any pyramid is $V = \frac{1}{3} h (A + a + \sqrt{Aa})$.

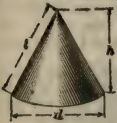
## THE WEDGE

The *wedge*, whether with a blunt edge as $ABCD\text{-}abcd$, or with a sharp edge as $ABCD\text{-}a'b'$, is a special form of the trapezoid, as the ends $abcd$, or $a'b'$ are parallel to the base $ABCD$. In the blunt wedge, $V = \frac{1}{2} fh(m+n)$ and in the sharp wedge $V = \frac{1}{2} fnh$, as $m = 0$. In the latter case, $h = Bb'$.


## THE CONE

A *cone*, Fig. 1, is a solid generated by a straight line, one end of which passes through a fixed point, called the *apex* while the other end is free to move around the perimeter of a closed curve, known as the *base*. Cones are regular when the base is a circle and are right or oblique according as the axis is at right angles to or inclined to the base.

FIG. 1

The common form of cone, as shown in accompanying figure, is the *right regular cone of revolution*, which may be


considered to have been generated by the revolution of a right-angled triangle about one side. Its base is a circle and its axis is perpendicular to the center of the base.

FIG. 2

The surface of the cone is $S = \pi r l = \frac{1}{2}\pi dl = 3.1416 rl = 1.5708 dl$.

The total surface, $T = \pi r l + \pi r^2 = \pi r \sqrt{r^2 + h^2} + \pi r^2 = \pi r (l + r)$ $= \pi r (\sqrt{r^2 + h^2} + r)$

The volume,

$$V = \frac{1}{3}A h = \frac{\pi}{12}d^2 h = \frac{P^2}{12\pi}h = \frac{\pi}{3}r^2 h = .2618 d^2 h = .0265 P^2 h = 1.0472 r^2 h.$$

**Frustum of Cone.**—When, as in Fig. 2, the cutting plane is parallel to the base of the cone

$$S = \frac{1}{2}l(P + p) = \frac{1}{2}\pi l(D + d), \text{ and } T = \frac{1}{2}\pi[l(D + d) + \frac{\pi}{4}\frac{1}{2}(D^2 + d^2)]$$

$$V = \frac{1}{4}\pi(D^2 + d^2 + Dd)\frac{h}{3} = .2618 h(D^2 + d^2 + Dd)$$

---

# PLANE TRIGONOMETRY

## DEFINITIONS

*Plane trigonometry* treats of the solution of plane triangles. In every triangle there are six parts—three sides and three angles. These parts are so related that when three of the parts are given, one being a side, the other parts may be found.

An angle is measured by the arc included between its sides, the center of the circumference being at the vertex of the angle.

For measuring angles, the circumference is divided into 360 equal parts, called *degrees;* each degree is divided into 60 equal parts called *minutes;* and each minute is divided into 60 equal parts called *seconds.* Divisions smaller than a second are expressed in decimal parts of that unit; thus, 24.56″.

A *quadrant* is one-fourth the circumference of a circle, or 90°.

The *complement* of an arc is 90° minus the arc; the arc *DC*, Fig. 1, is the complement of the arc *BC*, and the angle *DOC* is the complement of the angle *BOC*.

The *supplement* of an arc is 180° minus the arc; the arc *AE* is the supplement of the arc *BDE*, and the angle *AOE* is the supplement of the angle *BOE*.

FIG. 1

In trigonometry, instead of comparing the angles of triangles or the arcs that measure them, the trigonometric functions, known as the sine, cosine, tangent, cotangent, secant, and cosecant, are compared.

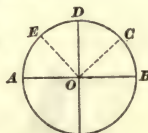
The *sine* of an arc is the perpendicular let fall from one extremity of the arc on the diameter that passes through the other extremity. Thus, *CD*, Fig. 2, is the sine of the arc *AC*.

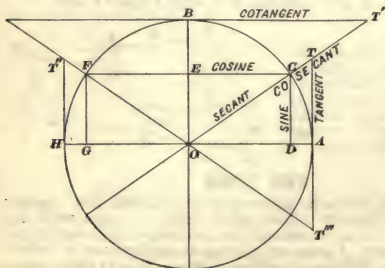
FIG. 2

The *cosine* of an arc is the sine of its complement; or it is the distance from the foot of the sine to the center of the circle. Thus, *CE* or *OD* equals the cosine of arc *AC*.

The *tangent* of an arc is a line that is perpendicular to the radius at one extremity of an arc and limited by a line passing through the center of the circle and the other extremity. Thus, *AT* is the tangent of *AC*.

The *cotangent* of an arc is equal to the tangent of the complement of the arc. Thus, *BT′* is the cotangent of *AC*.

The *secant* of an arc is a line drawn from the center of the circle through one extremity of the arc, and limited by a tangent at the other extremity. Thus, *OT* is the secant of *AC*.




The *cosecant* of an arc is the secant of the complement of the arc. Thus, $OT'$ is the cosecant of $AC$.

The *versed sine* of an arc is that part of the diameter included between the extremity of the arc and the foot of the sine. $DA$ is the versed sine of $AC$.

The *coversed sine* is the versed sine of the complement of the arc. Thus, $BE$ is the coversed sine of $AC$.

## FUNDAMENTAL RELATIONS

If $x$ is any angle, the fundamental relations that its trigonometric functions sustain to one another are:

$$\sin^2 x + \cos^2 x = 1$$
$$\tan x = \frac{\sin x}{\cos x}$$
$$\cot x = \frac{\cos x}{\sin x}$$
$$\cot x = \frac{1}{\tan x}$$

$$\sec x = \frac{1}{\cos x}$$
$$\operatorname{cosec} x = \frac{1}{\sin x}$$
$$\sec^2 x = 1 + \tan^2 x$$
$$\operatorname{cosec}^2 x = 1 + \cot^2 x$$
$$\operatorname{vers} x = 1 - \cos x$$
$$\operatorname{covers} x = 1 - \sin x$$

The tangent and cotangent of the same angles are reciprocals of each other; so also are the secant and cosine; and the cosecant and sine.

The value of the sine and cosine cannot be greater than 1. Tangents and cotangents may have any value from 0 to ∞. Secants and cosecants may have any value between 1 and ∞. Versed sines and coversed sines may have any value between 0 and 2.

## SIGNS OF TRIGONOMETRIC FUNCTIONS

The various trigonometric functions have signs; that is, they are + or −, depending on the magnitude of the angle.

Sines and cosecants of angles between 0° and 180° are +; and those of angles between 180° and 360° are −.

Cosines and secants of angles between 0° and 90° and between 270° and 360° are +; and those of angles between 90° and 270° are −.

Tangents and cotangents of angles between 0° and 90° and between 180° and 270° are +; and those of angles between 90° and 180° and between 270° and 360° are −.

Versed sines and coversed sines are always + regardless of the magnitude of the angle.

## FUNCTIONS OF ANGLES BETWEEN 90° AND 180°

In the solution of obtuse-angled triangles, it is commonly necessary to have to find the functions of an angle of more than 90°. This may readily be done if it is recalled that the functions of an angle of more than 90°. This may readily be function of its supplement. Thus

| | |
|---|---|
| sine 110° = sine of 70° | cosine 110° = cosine 70° |
| tangent 110° = tangent of 70° | cotangent 110° = cotangent of 70° |
| secant 110° = secant of 70° | cosecant 110° = cosecant of 70° |

Thus, if it is desired to find the sine of an angle of 120° 30′, look for the sine of 180° − 120° 30′, or 59° 30′, and similarly for the other functions. In dealing with angles of more than 90° attention should be paid to the sign of the function.

## FUNCTIONS OF 90° + A

| | |
|---|---|
| $\sin (90° + A) = \cos A$ | $\cot (90° + A) = -\tan A$ |
| $\tan (90° + A) = -\cot A$ | $\sec (90° + A) = -\csc A$ |
| $\cos (90° + A) = -\sin A$ | $\csc (90° + A) = \sec A$ |

## FUNCTIONS OF 180° − A AND OF 180° + A

| | |
|---|---|
| $\sin (180° - A) = \sin A$ | $\sin (180° + A) = -\sin A$ |
| $\tan (180° - A) = -\tan A$ | $\tan (180° + A) = \tan A$ |
| $\cos (180° - A) = -\cos A$ | $\cos (180° + A) = -\cos A$ |
| $\cot (180° - A) = -\cot A$ | $\cot (180° + A) = \cot A$ |
| $\sec (180° - A) = -\sec A$ | $\sec (180° + A) = -\sec A$ |
| $\csc (180° - A) = \csc A$ | $\csc (180° + A) = -\csc A$ |

## FUNCTIONS OF (A+B) AND OF (A−B)

$$\sin (A+B) = \sin A \cos B + \cos A \sin B$$
$$\sin (A-B) = \sin A \cos B - \cos A \sin B$$
$$\cos (A+B) = \cos A \cos B - \sin A \sin B$$
$$\cos (A-B) = \cos A \cos B + \sin A \sin B$$
$$\tan (A+B) = \frac{\tan A + \tan B}{1 - \tan A \tan B}$$
$$\tan (A-B) = \frac{\tan A - \tan B}{1 + \tan A \tan B}$$

## FUNCTIONS OF 2A AND OF ½A

$$\sin 2A = 2 \sin A \cos A$$

$$\cos 2A = \cos^2 A - \sin^2 A$$

$$\cos 2A = 2 \cos^2 A - 1$$

$$\cos 2A = 1 - 2 \sin^2 A$$

$$\tan 2A = \frac{2 \tan A}{1 - \tan^2 A}$$

$$\sin \tfrac{1}{2}A = \sqrt{\frac{1 - \cos A}{2}}$$

$$\cos \tfrac{1}{2}A = \sqrt{\frac{1 + \cos A}{2}}$$

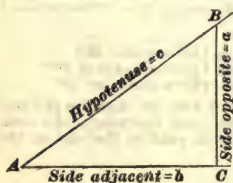
$$\tan \tfrac{1}{2}A = \sqrt{\frac{1 - \cos A}{1 + \cos A}}$$

$$\tan \tfrac{1}{2}A = \frac{1 - \cos A}{\sin A}$$

## SUMS AND DIFFERENCES OF FUNCTIONS

$$\sin A + \sin B = 2 \sin \tfrac{1}{2}(A+B) \cos \tfrac{1}{2}(A-B)$$
$$\sin A - \sin B = 2 \sin \tfrac{1}{2}(A-B) \cos \tfrac{1}{2}(A+B)$$
$$\cos A + \cos B = 2 \cos \tfrac{1}{2}(A+B) \cos \tfrac{1}{2}(A-B)$$
$$\cos A - \cos B = 2 \sin \tfrac{1}{2}(A+B) \sin \tfrac{1}{2}(B-A)$$
$$\tan A + \tan B = \frac{\sin (A+B)}{\cos A \cos B}$$
$$\tan A - \tan B = \frac{\sin (A-B)}{\cos A \cos B}$$
$$\sin^2 A - \sin^2 B = \sin (A+B) \sin (A-B)$$
$$\cos^2 A - \cos^2 B = \sin (A+B) \sin (B-A)$$
$$\cos^2 A - \sin^2 B = \cos (A+B) \cos (A-B)$$

## SOLUTION OF RIGHT-ANGLED TRIANGLES



There are six parts in every triangle and if three of them are known the other three may be determined by calculation, provided one of the three known parts is a side. In the case of a right-angled triangle, one of the angles is 90°, but two other parts, one of them a side, are necessary for its solution. Three angles do not determine a triangle, because all triangles whose sides are parallel each to have the same angles but sides of different length.

In right-angled triangles, the following relations between the angles and sides prevail:

$$\sin A = \frac{\text{side opposite}}{\text{hypotenuse}} = \frac{a}{c} \qquad \cot A = \frac{\text{side adjacent}}{\text{side opposite}} = \frac{b}{a}$$

$$\cos A = \frac{\text{side adjacent}}{\text{hypotenuse}} = \frac{b}{c} \qquad \sec A = \frac{\text{hypotenuse}}{\text{side adjacent}} = \frac{c}{b}$$

$$\tan A = \frac{\text{side opposite}}{\text{side adjacent}} = \frac{a}{b} \qquad \text{cosec } A = \frac{\text{hypotenuse}}{\text{side opposite}} = \frac{c}{a}$$

$$\text{vers } A = 1 - \frac{b}{c} \qquad\qquad \text{covers } A = 1 - \frac{a}{c}$$

## RELATIONS BETWEEN ANGLES AND SIDES OF RIGHT-ANGLED TRIANGLES

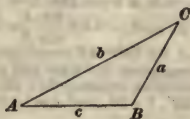
| Given | Required | Formula | Given | Required | Formula |
|-------|----------|---------|-------|----------|---------|
| $a, A$ | $B, b, c$ | $\begin{cases} B = 90° - A \\ b = a \cot A \\ c = \dfrac{a}{\sin A} = a \csc A \end{cases}$ | | | $\begin{cases} \tan A = \dfrac{a}{b} \\ \tan B = \dfrac{b}{a}, \\ \text{or } B = 90° - A \\ c = \sqrt{a^2 + b^2} \\ c = \dfrac{a}{\sin A} = a \csc A \end{cases}$ |
| $a, B$ | $A, b, c$ | $\begin{cases} A = 90° - B \\ b = a \tan B \\ c = \dfrac{a}{\cos B} = a \sec B \end{cases}$ | $a, b$ | $A, B, c$ | |
| $c, A$ | $B, a, b$ | $\begin{cases} B = 90° - A \\ a = c \sin A \\ b = c \cos A \end{cases}$ | | | $\begin{cases} \sin A = \dfrac{a}{c} \\ \cos B = \dfrac{a}{c} \\ \text{or } B = 90° - A \\ b = \sqrt{c^2 - a^2} \\ \quad = \sqrt{(c+a)(c-a)} \\ b = a \cot A \end{cases}$ |
| | | | $a, c$ | $A, B, b$ | |

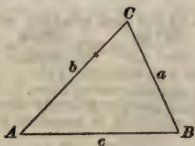
**Area.**—The area of a right-angled triangle is equal to one-half the product of the base by the altitude, or area = $\frac{1}{2} ab$.

The area is also equal to one-half the product of any two sides into the sine of the angle between them. Thus, if the angle $A$ and the sides $c$ and $b$ are given, area = $\frac{1}{2} cb \sin A$.

## SOLUTION OF OBLIQUE-ANGLED TRIANGLES

The following relations between the sides and angles apply to all triangles, but are of particular service in solving those with oblique angles:





1. *The sides of any plane triangle are proportional to the sines of the angles opposite.*

$$a : b = \sin A : \sin B$$
$$a : c = \sin A : \sin C$$
$$b : c = \sin B : \sin C$$

2. *Any side of a plane triangle equals the sum of the products of each of the other sides into the cosine of the angle that it makes with the first side.*

$$a = b \cos C + c \cos B$$
$$b = a \cos C + c \cos A$$
$$c = a \cos B + b \cos A$$

3. *The square of any side of a plane triangle equals the sum of the squares of the other two, minus twice their product into the cosine of their included angle.*

$$a^2 = c^2 + b^2 - 2bc \cos A$$
$$b^2 = a^2 + c^2 - 2ac \cos B$$
$$c^2 = a^2 + b^2 - 2ab \cos C$$

4. *The sum of any two sides of a plane triangle is to their difference, as the tangent of one-half the sum of the angles opposite them is to the tangent of one-half their difference.*

$$a + b : a - b = \tan \tfrac{1}{2}(A + B) : \tan \tfrac{1}{2}(A - B)$$
$$a + c : a - c = \tan \tfrac{1}{2}(A + C) : \tan \tfrac{1}{2}(A - C)$$
$$b + c : b - c = \tan \tfrac{1}{2}(B + C) : \tan \tfrac{1}{2}(B - C)$$

5. *The cosine of any angle of a plane triangle is equal to the sum of the squares of the adjacent sides minus the square of the side opposite, the whole divided by twice the product of the adjacent sides.*

$$\cos A = \frac{b^2 + c^2 - a^2}{2bc}$$

$$\cos B = \frac{a^2 + c^2 - b^2}{2ac}$$

$$\cos C = \frac{a^2 + b^2 - c^2}{2ab}$$

6. *The area of any plane triangle is equal to one-half the product of any two sides into the sine of the included angle.*

$$\text{Area} = \tfrac{1}{2}cb \sin A = \tfrac{1}{2}ac \sin B = \tfrac{1}{2}ab \sin C$$

7. *The area of any plane triangle is equal to the square root of the continued product of one-half its perimeter into one-half its perimeter minus each side separately.*

If the perimeter, $a + b + c = p$, then,

$$\text{Area} = \sqrt{\tfrac{1}{2}p(\tfrac{1}{2}p - a)(\tfrac{1}{2}p - b)(\tfrac{1}{2}p - c)}$$

## PRACTICAL EXAMPLES

1. *Having given two sides and the included angle, to find the other side and remaining angles.*—Let $b = 30$, $c = 20$, and $A = 38° 20'$; required $a$, $B$, and $C$. Find the angle $B$ from the third formula of the fourth relation, which may be transposed to $\tan \frac{1}{2}(B-C) = \tan \frac{1}{2}(B+C) \times \frac{b-c}{b+c}$. In this $B + C = 180° - A = 180° - 38° 20' = 141° 40'$, and $\frac{1}{2}(B+C) = 70° 50'$; $B - C$ is unknown; $b + c = 30 + 20 = 50$, and $b - c = 30 - 20 = 10$. By substitution, $\tan \frac{1}{2}(B-C) = 2.87700 \times \frac{10}{50} = .57540$. From this $\frac{1}{2}(B-C) = 29° 55'$ (very nearly), and $B - C = 29° 55' \times 2 = 59° 50'$.

$$B + C = 141° 40'$$
$$B - C = 59° 50'$$

By addition, $2B = 201° 30'$
By division, $B = 100° 45'$

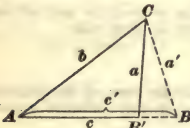
From this $A + B = 38° 20' + 100° 45' = 139° 5'$, and $C = 180° - (A+B) = 180° - 139° 5' = 40° 55'$.

Find the side $a$ from the first formula of the first relation, which may be transposed to read, $a = b \times \frac{\sin A}{\sin B} = 30 \times \frac{\sin 38° 20'}{\sin 100° 45'} = 30 \times \frac{.62024}{.98245} = 18.94$. Remember that $\sin 100° 45' = \sin (180° - 100° 45') = \sin 79° 15'$.

2. *Having given two sides and the angle opposite one of them, to find the other side and remaining angles.*—Let the given parts of the triangle shown in Fig. 1, be $A = 38° 20'$, $b = 30$, and $a = 18.94$; from which it is required to find $c$, $B$, and $C$.

Find the angle $B$ from the first formula of the first relation, which transposed is $\sin B = \frac{b}{a} \times \sin A = \frac{30.00}{18.94} \times \sin 38° 20' = \frac{30.00}{18.94} \times .62024 = .98245$; whence $B = 79° 15'$ or $100° 45'$. Unless the shape of the triangle is actually known it is impossible to tell which of these values of $B$ should be taken. In fact, both of them are correct, as a study of the accompanying figure will show. As only $A$, $b$, and $a$, are fixed, it is apparent that $a$ may occupy either position $CB$ or $CB'$ and yet have the same value, 18.94. Such being the case, the angle at $B$ may be (for the position $CB = a' = 18.94$) $CBA = 79° 15'$, or (for the position $CB' = a = 18.94$) $CB'A = 100° 45'$. Hence, angle $C = 180° - (A+B) = 180° - (38° 20' + 79° 15') = 180° - 117° 35' = 62° 25'$, or $C = 180° - (38° 20' + 100° 45') = 180° - 139° 5' = 40° 55'$.

Fig. 1

The side $c$ may now be found from the second formula of the first relation, which may be transposed to read $c = a \frac{\sin C}{\sin A}$, and taking the two values of the angle $C$, $c = 18.94 \times \frac{\sin 62° 25'}{\sin 38° 20'} = 18.94 \times \frac{.88634}{.62024} = 27.07$


or
$$c = 18.94 \times \frac{\sin 40° \, 55'}{\sin 38° \, 20'} = 18.94 \times \frac{.65496}{.62024} = 20$$

Thus two solutions of this triangle are possible; in the first case, $B = 79° \, 15'$, $C = 62° \, 25'$, $c = 27.07$, and in the second case, $B = 100° \, 45'$, $C = 40° \, 55'$, $c = 20$.

3. *Having given two angles and any side, to find the other angle and the other two sides.*—Let $A = 38° \, 20'$, $B = 100° \, 45'$, $a = 18.94$; to find the remaining angle $C$ and the other sides $b$ and $c$.

Find $C$ from the relation $C = 180° - (A + B) = 180° - (38° \, 20' + 100° \, 45')$ $= 180° - 139° \, 5' = 40° \, 55'$.

The sides may now be found from the first and second formulas given in the first relation after these have been transposed.
$$b = a \frac{\sin B}{\sin A} = 18.94 \times \frac{\sin 100° \, 45'}{\sin 38° \, 20'} = 18.94 \times \frac{.98245}{.62024} = 30$$
$$c = a \frac{\sin C}{\sin A} = 18.94 \times \frac{\sin 40° \, 55'}{\sin 38° \, 20'} = 18.94 \times \frac{.65496}{.62024} = 20$$

4. *Having given the three sides to find the three angles.*—Let $a = 18.94$, $b = 30$, and $c = 20$; required the angles $A$, $B$, and $C$. Using the formulas given in the fifth relation, then $C = 180° - (A + B)$.
$$\cos A = \frac{b^2 + c^2 - a^2}{2bc} = \frac{30^2 + 20^2 - 18.94^2}{2 \times 30 \times 20} = .78440, \text{ and } A = 38° \, 20'$$
$$\cos B = \frac{a^2 + c^2 - b^2}{2ac} = \frac{18.94^2 + 20^2 - 30^2}{2 \times 18.94 \times 20} = -.18648, \text{ and } B = 100° \, 45'$$
$$C = 180° - (A + B) = 180° - (38° \, 20' + 100° \, 45') = 40° \, 55'$$

Note that the angle corresponding to the cosine .18648 is either $79° \, 15'$ or $100° \, 45'$. By referring to the section Signs of Trigonometric Functions, it will be seen that when the cosine is minus, as it is in this case $(-.18648)$, the angle is between $90°$ and $270°$; hence, the value $B = 100° \, 45'$ is taken.

This example is readily solved by the solution of two right-angled triangles, as shown in Fig. 2. Let fall a perpendicular $CD$ from the opposite vertex $C$ upon the longest side $AB$ dividing it into two segments $AD = m$ and $DB = n$. From geometry, $m + n : b + a = b - a$

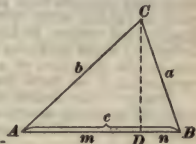


Fig. 2

$: m - n$, and as $m + n = c$, $m - n = \frac{(b + a)(b - a)}{c}$. Combining the value of $m - n$ thus obtained with that of $m + n = c$, the values of $m$ and $n$ may be found. In the right-angled triangles $ACD$ and $BCD$, $b$ and $m$ and $a$ and $n$, respectively, are given, from which the angles $A$ and $B$ may be calculated; angle $C$ found by subtracting the sum of angles $A$ and $B$ from $180°$.

Using the values for the sides, $a = 18.94$, $b = 30$, and $c = 27.066$,
$$m - n = \frac{(30 + 18.94) \times (30 - 18.94)}{27.066} = \frac{48.94 \times 11.06}{27.066} = 19.998.$$

Then

|  |  |  |  |
|---|---|---|---|
| | $m + n = 27.066$ | | $m + n = 27.066$ |
| | $m - n = 19.998$ | | $m - n = 19.998$ |
| By addition | $2m = 47.064$ | By subtraction | $2n = \; 7.068$ |
| | $m = 23.532$ | | $n = \; 3.534$ |

In the triangle $ACD$, $\cos A = \frac{m}{b} = \frac{23.532}{30} = .78440$. Whence $A = 38° \, 20'$.

In the triangle $DCB$, $\cos B = \frac{n}{a} = \frac{3.534}{18.94} = .18659$. Whence $B = 79° \, 15'$.
$$C = 180° - (A + B) = 180° - 117° \, 35' = 62° \, 25'$$

Tables of natural and logarithmic trigonometric functions will be found at the end of the volume; each table is preceded by the necessary explanations for its use.

# SURVEYING

## THE COMPASS

### GENERAL DESCRIPTION

*Surveying* is an extension of mensuration, and, as ordinarily practiced, may be divided into surface work, or *ordinary surveying*, and underground work, or *mine surveying*. With slight modifications, the instruments employed in both are the same, and consist of a compass—if the work is of little importance, and accuracy is not required—a transit, level, transit and level rods, steel tape or chain, and measuring pins, and sometimes certain accessory instruments, as clinometers or slope levels, dipping needles, etc., as will be described later.

The *compass* may be either a pocket compass, or a surveyor's compass, and may be used while held in the hand, or upon a tripod. The Jacob's staff, convenient for use on the surface, is useless in the mine. As the compass cannot be sighted accurately on an object, cannot be read closer than 30′, except by guess, and may be deflected from its true course as much as 2° or 3° by the iron in the rails or water pipes or by electric currents, it is obvious that bearings and angles determined through its use cannot be relied on as being within 15′ of the truth and they may be very much more in error. As present day surveying requires that any angle be known within 1 min. and in special cases, such as tunnel work, within 30″ or even 20″ or 15″, the compass is now no longer used except, in emergencies, when a transit is not available. However, in driving room necks far enough for the permanent sights, in obtaining a rough idea of the direction of a heading, and, on the surface, in connection with the rerunning of old land lines, the compass has its uses.

Owing to the length of time taken by the needle to settle so that it can be read, an accurate transit survey can commonly be made in less time than an inaccurate one with the compass.

### COMPASS ADJUSTMENTS

When adjusting the *levels*, first bring the bubbles into the center by the pressure of the hand on different parts of the plate, and then turn the compass half way around. Should the bubbles run to the ends of the tubes, those ends are the higher; these should then be lowered by tightening the screws immediately under, and loosening those under the lower ends until, by estimation, the error is half removed. The plate should again be leveled and the first operation repeated until the bubbles will remain in the center during an entire revolution of the compass.

The *sights* may next be tested by observing, through the slits, a fine hair or thread, made exactly vertical by a plumb. Should the hair appear on one side of the slit, the sight must be adjusted by filing off its under surface on the side that seems the higher.

The *needle* is adjusted in the following manner: Having the eye nearly in the same plane with the graduated rim of the compass circle, with a small splinter of wood, or a slender iron wire, bring one end of the needle in line with any prominent division of the circle, as the 0 or 90° mark, and notice if the other end corresponds with the degree on the opposite side. If it does, the needle is said to cut opposite degrees; if not, bend the center pin by applying a small brass wrench, furnished with most compasses, about ⅛ in. below the point of the pin, until the ends of the needle are brought into line with the opposite degrees. Then, holding the needle in the same position, turn the compass half way around, and note whether it now cuts opposite degrees; if not, correct half the error by bending the needle, and the remainder by bending the center pin. The operation must be repeated until perfect reversion is secured in the first position. This being obtained, it may be tried on another quarter of the circle; if any error is there manifested, the correction must be made in the center pin only, the needle being already straightened by the previous operation. When again made to cut, it should be tried on the other quarters of the circle, and corrections made in the same manner until the error is entirely removed, and the needle will reverse in every point of the divided circle.

## USING THE COMPASS

When using the compass, the surveyor should keep the south end toward his person, and read the bearings from the north end of the needle. In the surveyor's compass the position of the E and W letters on the face of the compass are reversed from their natural position, in order that the direction of the sight may be correctly read.

The compass circle being graduated to $\frac{1}{2}°$, a little practice will enable the surveyor to read the bearings to quarters—estimating with his eye the space bisected by the point of the needle.

The compass is divided into quadrants, and 0 is placed at the north and south ends; 90° is placed at the E and W marks, and the graduations run right and left from the 0 to 90°. When reading the bearing, the surveyor will notice that if the sights are pointed in a NW direction, the north end of the needle, which always points approximately north, is to the right of the front sight or front end of the telescope, and, as the number of degrees is read from it, the letters marking the cardinal points of the compass read correctly. If the E, or east, mark were on the right side of the circle, a NW course would read NE. This same remark applies to all four quadrants. The compass should always be in a level position.

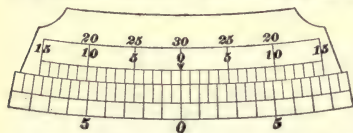
If all the corners of a field can be seen from a central point, the survey can be made by setting up at that point, and with one corner as a backsight, taking all the other corners as foresights, and by measuring from this point to all of the corners; or the compass can be set up at any corner and a line of survey run around the field. This latter method is called *meandering*. Both methods will give the same result when plotted; but the first is much quicker, as the boundaries of a tract are frequently overgrown with bushes that must be cleared to allow a sight; while a central point can frequently be found that will allow a free sight to all the corners, and the distance can be measured by tape, or stadia. As the central point is nearer the corners than they are to one another, a shorter distance must be chained or cut in the case of a central set-up.

## MAGNETIC VARIATION

*Magnetic declination*, or *variation*, of the needle is the angle made by the magnetic meridian with the true meridian or true north and south line. It is east or west according as the north end of the needle lies east or west of the true meridian. It is not constant, but changes from year to year, and, for this reason, in rerunning the lines of a tract of land, from field notes of some years' standing, the surveyor makes an allowance in the bearing of every line by means of a vernier.

The declination, where a knowledge of it is necessary, should always be determined for the particular place and at the particular time where and when it is needed. Quite a number of the States in cooperation with the United States Coast and Geodetic Survey have established a true meridian by astronomical observations at each county seat. Information as to the location, etc., of the monuments marking the meridian may be obtained from the county surveyor, the recorder of deeds, or some one else in authority at the county court house. However, the variation thus obtained is only available for use a comparatively short distance either east or west of the county seat (assuming that the highest accuracy is desired), because on the average, there is in the United States, a change in the value of the declination of 1′ per mi. in the foregoing directions. From this, it is apparent that the declination at a place 30 mi. east or west of the county seat will probably vary 30′ from that at the monuments referred to. This difference of 30′ is within the limits between which the compass is ordinarily read. In proceeding north or south from the county seat, the change in declination is very much less than in an east or west direction. If the declination cannot be determined, a note should be made of the date of the survey, with a statement to the effect that the bearings are referred to the magnetic meridian, and these notes should appear on the map and should be incorporated in the deed if the survey was made preliminary to a transfer of property.

The United States Coast and Geodetic Survey, Washington, District of Columbia, issues from time to time tables and charts showing the declination at many points in the United States and outlying possessions, together with formulas by means of which the declination may be calculated with a high degree of accuracy at future times. These may be obtained from the Superintendent of the Survey.

**Reading the Vernier.**—The compass vernier, shown in the accompanying illustration, is usually so graduated that 30 spaces on it equal 31 on the limb of the instrument and, commonly, there are 15 spaces on each side of the 0 mark. It is read as follows: Note the degrees and half degrees on the limb of the instrument. If the space passed beyond the degree or half-degree mark by the zero mark on the vernier is less than one-half the space of $\frac{1}{2}°$ on the limb, the number of minutes is, of course, less than 15, and must be read from the lower row of figures. If the space passed is greater than one-half the spacing on the limb, the upper row of figures must be read. The line on the vernier that exactly coincides with a line on the limb is the mark that denotes the number of minutes. If the index is moved to the right, the minutes are read from the left half of the vernier; if moved to the left, they are read from the right side of the vernier.


**Turning Off the Variation.**—Moving the vernier to either side, and with it, of course, the compass circle attached, set the compass to any variation by placing the instrument on some well-defined line of the old survey, and by turning the tangent screw (slow-motion screw) until the needle of the compass indicates the same bearing as that given in the old field notes of the original survey. Then screw up the clamping nut underneath the vernier and run all the other lines from the old field notes without further alteration. The reading of the vernier on the limb gives the amount of variation since the original survey was made.

## FIELD NOTES FOR AN OUTSIDE COMPASS SURVEY

Call place of beginning Station 1.

| Stations | Bearings | Distances |
|---|---|---|
| 1–2 | N 35° E | 270.0 |

At 1+ 37 ft. crossed small stream 3 ft. wide.
At 1+116 ft. = first side of road.
At 1+131 ft. = second side of road.
At 1+137 ft. = blazed and painted pine tree, 3 ft. left, marked for a go-by.
Station 2 is a stake at foot of white-oak tree, blazed and painted on four sides for corner.

| | | |
|---|---|---|
| 2–3 | N 83½° E | 129.0 |

Station 3 is a stake-and-stones corner.

| | | |
|---|---|---|
| 3–4 | S 57° E | 222.0 |

3+ 64 ft. = center of small stream 2 ft. wide.
3+196 ft. = white oak go-by, 2 ft. right.
Station 4, cut stone corner.

| | | |
|---|---|---|
| 4–5 | S 34½° W | 355.0 |

4+174 ft. = ledge of sandstone 10 ft. thick, dipping 27° south.

| | | |
|---|---|---|
| 5–1 | N 56½° W | 323.0 |

5+274 ft. = ledge of sandstone 10 ft. thick, dipping 25° south (evidently continuation of same ledge as at 4+174).
Station 1 = place of beginning.

# THE TRANSIT

## GENERAL DESCRIPTION

The *transit* is the only instrument that should be used for measuring angles in any survey where accuracy is desired. The advantages of a transit over a vernier compass are mainly due to the use of a telescope. By its use, angles can be measured either vertically or horizontally, and, as the vernier is used throughout, extreme accuracy is secured.

Fig. 1 shows the interior construction of the sockets of a transit having two verniers to the limb, the manner in which it is detached from its spindle, and how it can be taken apart when desired. The limb *b* is attached to the main socket *c*, which is carefully fitted to the conical spindle *h*, and held in place by the spring catch *s*.

The upper plate *a*, carrying the compass circle, standards, etc., is fastened to the flanges of the socket *k*, which is fitted to the upper conical surface of the

main socket $c$. The weight of all the parts is supported on the small bearings of the end of the socket, as shown, so as to make as little friction as possible where such parts are being turned as a whole.

A small conical center, in which a strong screw is inserted from below, is brought down firmly on the upper end of the main socket $c$, thus holding the two plates of the instrument securely together, and, at the same time, allowing them to move freely around each other. The steel center pin on which the needle rests is held by the small disk fastened to the upper plate by two small screws above the conical center. The clamp to limb $df$, with clamp screw, is attached to the main socket. The instrument

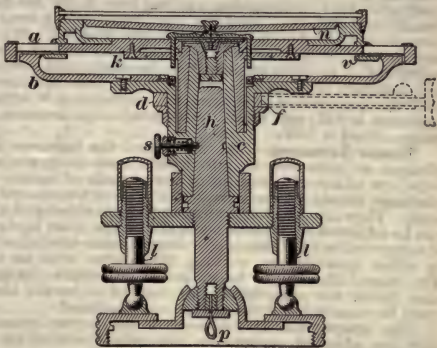


Fig. 1

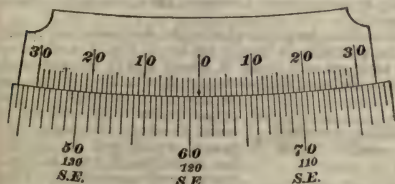
is leveled by means of the leveling screws $l$ and placed exactly over a point by means of the shifting center. The plummet is attached to the loop $p$.

**Transit Verniers.**—In transits, the limb or plate has two sets of concentric graduations, as shown in part in Fig. 2. The style of marking these graduations may be varied to suit the ideas of the surveyor, but the arrangement shown is a common and a good one. The same $0°$ point is used for both sets of the graduations and is placed near or under the eye end of the telescope. One set of graduations is continuous from this $0°$ to $360°$ toward the left. The other set begins at the same $0°$ point and increases to $90°$ at the left, decreases to $0°$ directly opposite the starting point, increases to $90°$ at the right of this point, and decreases to $0°$ at the starting point. The first described set of graduations is numbered continuously every $10°$ from $0°$ to $360°$. The inner row is numbered, in advancing order, every $10°$ from $0°$ to $90°$; thence it decreases by $10°$ to the $0°$ point; then it again increases by $10°$ to the $90°$ mark at the right; and then decreases by $10°$ to the starting point. This last set of graduations, known as *quadrant graduations*, is marked with an N at the $0°$ point, with E at the $90°$ point; and similarly with S and W at the second $0°$ and second $90°$ points, respectively. Further, as shown, at each marking, the letters N E, S E, S W, or N W are stamped on the plate at its proper quadrant. Thus the $0°$ of the continuous graduation is the same as the N on the quadrant graduation, the $90°$ of the continuous graduation is the same as the E of the quadrant, the $180°$ of the continuous graduation is the S of the quadrant, and the $270°$ of the continuous graduation is the W of the quadrant.


There are two transit verniers; one, known as *vernier A*, is placed as near as possible under the eye end of the telescope, and the other, known as *vernier B*, is placed directly opposite. These verniers are double, that is, they read both ways from the 0 mark so that angles deflected either to the right or left may be read. The vernier is commonly divided so that 30

Fig. 2

spaces on it are equal to 29 spaces on the limb of the transit. Each division of the vernier is, therefore, $\frac{1}{30}$, or, in other words, 1′ shorter than the $\frac{1}{2}°$ graduations on the limb. In Fig. 2, the reading is S $60°30'$ E (from the limb) $+13'$ (from the vernier) $=$ S $60°43'$ E. This is the quadrant reading from the inner row of graduations. The continuous vernier (outer row) reading is $119°$ (from the limb)

+17′ (from the vernier) = 119° 17′. It will be noted that the sum of the two readings is 60° 43′+119° 17′ = 180°. This summation proves and checks the readings. Had the quadrant reading been N 33° 18′ E, the continuous vernier should read 33° 18′. Had the quadrant reading been S 56° 39′ W, the continuous vernier should read 180°+56° 39′ = 236° 39′; and had the quadrant reading been N 76° 29′ W, the continuous vernier should read 360°−76° 19′ = 283° 31′. In other words, when the continuous vernier reads from 0° to 90°, the quadrant reading will be NE; when the continuous is between 90° and 180° the quadrant is SE; when the continuous is between 180° and 270° the quadrant is SW; and when the continuous is between 270° and 360° (or 0°), the quadrant is NW.

**Transit Telescope.**—The interior of the telescope is fitted up with a diaphragm or cross-wire ring to which cross-wires are attached. These cross-wires are either of platinum or as strands of spider web.· For inside work, platinum should be used, as spider web is translucent and cannot readily be seen. They are set at right angles to each other and are so arranged that one can be adjusted so as to be vertical and the other horizontal. This diaphragm is suspended in the telescope by four capstan-headed screws, and can be moved in either direction by working the screws with an ordinary adjusting pin. The transit should not be subjected to sudden changes in temperature that may break the cross-hairs. In case of a break, the cross-hair diaphragm must be removed and the broken wire replaced.

The intersection of the wires forms a very minute point, which, when they are adjusted, determines the optical axis of the telescope, and enables the surveyor to fix it upon an object with the greatest precision.

The imaginary line passing through the optical axis of the telescope is termed the *line of collimation*, and the operation of bringing the intersection of the wires into the optical axis is called the *adjustment of the line of collimation*.

All screws and movable parts should be covered, so that acid water and dust will be kept out. If this is not done, the mine work will destroy a transit. The vertical circle on the transit may be a full circle or a segment. The former is to be preferred, as it is always ready without intermediate clamp screws.

## TRANSIT ADJUSTMENTS

The use of a transit tends to disarrange some of its parts, which detracts from the accuracy of its work, but in no way injures the instrument itself. Correcting this disarrangement of parts is called *adjusting the transit*.

1. *To make the level tubes parallel to the vernier plate.*—Plant the feet of the tripod firmly in the ground. Turn the instrument until one of the levels is parallel to a pair of opposite leveling screws; the other level will be parallel to the other pair. Bring the bubble in each tube to the middle with the pair of leveling screws to which the tube is parallel. Next turn the vernier plate half way around; that is, revolve it through an angle of 180°. If the bubbles have remained in the middle of the tubes, the levels are in proper adjustment. If they have not remained so, but have moved toward either end, bring them half way back to the middle of the tubes by means of the capstan-headed screws attached to the tubes, and the rest of the way back by the leveling screws. Again turn the vernier plate through 180°, and if the bubbles do not remain at the middle of the tubes, repeat the correction. Sometimes the adjustment is made by one trial, but usually it is necessary to repeat the operation. Each level must be adjusted separately.

2. *To make the line of collimation perpendicular to the horizontal axis that supports the telescope.*—With the instrument firmly set at A, Fig. 1, and carefully leveled, sight to a pin or tack set at a point B, about 400 ft. distant, and on level, or nearly level, ground. Reverse the telescope; that is, turn it over on

its axis until it points in the opposite direction, and set a point at about the same distance, which will be at D, for example, if this adjustment needs correction. Un-
FIG. 1

clamp the vernier plate, and, without touching the telescope, revolve the instrument about its vertical axis sufficiently far to take another sight upon the point B. Then turn the telescope on its axis and locate a third point, as at C. Measure the distance CD, and at E, one-fourth of the distance from C to D, set the pin or tack. Move the cross-hairs, by means of the capstan-headed screws, until the vertical hair exactly covers the pin at E, being careful to move it in the opposite direction from that in which it appears it should be

moved. Having done this, and then having reversed the telescope, the line of sight will not be at the point $B$, but at $G$, a distance from $B$ equal to $CE$. Again sight to $B$, then reverse, and the pin will be at $F$ in the same straight line with $AB$. It may be necessary to repeat the operation to secure an exact adjustment.

3. *To make the horizontal axis of the telescope parallel to the vernier plate, so that the line of collimation will revolve in a vertical plane.*—Sight to some point $A$, Fig. 2, at the top of a building, so that the telescope will be elevated at a large angle. Depress the telescope and set a pin on the ground below at a point $B$. Loosen the clamp, turn over the telescope, and turn the plate around sufficiently far to take an approximately accurate sight upon the point $A$. Then clamp the instrument and again take an exact sight to the point $A$. Next depress the telescope, and set another pin on the ground, which will come at $C$. The distance $BC$ is double the error of adjustment. Correct the error by raising or lowering one end of the telescope axis by means of a small screw placed in the standard for that purpose. The amount the screw must be turned is determined only by repeated trials.

FIG. 2

4. *To make the axis of the attached level of the telescope parallel to the line of collimation.*—Drive two stakes at equal distances from the instrument and in exactly opposite directions. Level the plate carefully, and clamp the telescope in a horizontal position, or as nearly so as possible. Sight to a rod placed alternately upon each stake, and have the stakes driven down until the rod reading is the same on both stakes. When this condition is reached, the heads of the stakes are at the same level. Then move the instrument beyond one stake and set it up so that it will be in line with both stakes. Level the plate again and elevate or depress the telescope so that, when a sight is taken to the rod held on first one stake and then on the other, the reading will be alike on both. In this position, the line of collimation is level, and the bubble in the level attached to the telescope should stand in the center of the bubble tube. If it does not, bring it to the center by turning the nuts at the ends of the tube, being careful at the same time to keep the telescope in the position that gives equal rod readings on both stakes.

# CHAIN, STEEL TAPE, AND PINS

The *chain* is probably the earliest form of distance-measuring instrument. The original surveyor's or Gunters chain, was 66 ft. or 4 rd. in length and was composed of 100 li., each 7.92 in. long. This form of chain is no longer used, but is useful in preliminary work in locating old corners from descriptions in early deeds where distances are expressed in rods (poles, perches, or chains). The engineer's chain composed of 100 li. each 1 ft. long is also falling into disuse except for railroad work. Any chain is so liable to abrasion at the numerous joints and to bending, that distances measured with it cannot be relied on to be accurate within the limits demanded by modern engineering. A 100-ft. chain has 800 wearing surfaces, and should each one of these be worn but $\frac{1}{160}$ in. after several season's work, the chain will be 100 ft. 8 in. (100.67 ft.) in length, and each full 100 ft. measured with it will be recorded as but 99.34 ft. Similarly, bends or kinks shorten the chain so that the distances measured with it are recorded as being too great.

When used at all, the chain should be made of annealed steel wire, each link exactly 1 ft. in length. The links should be so made as to reduce the liability to kink to a minimum. All joints should be brazed, and handles at each end of **D** shape, or modifications of **D** shape, should be provided. These handles should be attached to short links at each end, and the combined length of each of these short links and one handle should be exactly 1 ft. The handles should be attached to the short link in such a manner that the chain may be slightly lengthened or shortened by screwing up a nut at the handle. It should be divided every 10 ft. with a brass tag, on which either the number of points represents the number of tens from the front end, or the number of tens may be designated by figures stamped on the tags.

When a chain is purchased, one that has been warranted as "Correct, U. S. Standard," should be selected, and, before using it, it should be stretched on a level surface, care being taken that it is straight, and no kinks in it, and the extremities marked by some permanent mark. These marks can be used in the future to test the chain. It should be tested frequently, and the length kept to the standard as marked when it was new.

Ordinarily, the chain should be held horizontally, and if either end is held above the ground, a plumb-bob and line should be used to mark the end of the chain on the ground. If used on a regular slope, the chain may be stretched along the ground, and, by having the amount of inclination, the horizontal and vertical distances may either be calculated or found in the Traverse Table.

The *steel tape*, which has superseded the chain, is simply a ribbon of steel not so high in carbon as to be brittle and liable to snap on a short bend, nor of so soft a steel that it will stretch when strongly pulled. Tapes are made of a standard or exact length at a given temperature, say 60° F., and under a certain tension, say, 15 lb. At higher temperatures or under greater pull the tape expands, and distances measured with it are less than the true ones. At lower temperatures or under less tension, the tape contracts and distances measured with it are too long. When a tape is hung unsupported between two points it forms a curve, called a *catenary*, and measures a greater distance between the points than if the tape formed a straight line. However, the apparent shortening of the distance between two points, owing to the tape being subject to more than the normal tension, may be offset by the lengthening of the distance due to sag in the unsupported tape. For every span, there is a corresponding tension where the errors balance, and this tension should be ascertained and used in practice. The errors due to expansion and contraction, arising from changes in temperature, cannot be compensated and must be corrected for in all accurate work. It should be noted that the temperature of the average mine is about 65° and being essentially the same as that at which the tape was graduated, no allowance for expansion or contraction is generally necessary in mine work.

Steel tapes are of two general kinds, and are commonly named from their length, as a 100-ft. tape, a 400-ft. tape, etc. The 50-ft. and 100-ft. tapes are about ⅜ in. wide, coil or wind up in a leather case or upon a small single-handed reel, and, for surveyor's use, are divided throughout their length into feet, tenths, and hundredths.

The steel tape, proper, is a narrow band of metal about one-third the width of the 100-ft. tape and considerably thicker, which is wound upon a wooden or iron reel like a spool. These tapes may be made in any length, but those 400 ft. long appear to be in most general use. The tape is commonly graduated every 5 ft. on brass sleeves soldered upon it. Distances are read to the nearest 5 ft. from the tape and intermediate distances measured with a pocket tape graduated in hundredths of a foot. Sometimes before the 0 mark there is an extra set of divisions into feet, the first foot being further divided into tenths. In this case, the scale for determining the hundredths need be very short, say a tenth or two in length. In use, a handle with a swivel joint is fixed in an eye at the 0 end and the tape unwound from the reel for the desired or required distance, but is not removed from the reel unless a distance equal to that of the tape is to be measured many times. In this case, a second handle may be fixed in the eye at the outer end of the tape.

In order to repair breaks that may occur in the field, clamps are made to hold the broken ends together. Brass sleeves that may be brazed around broken ends by the surveyor or by a competent gunsmith may be purchased. To keep a mark upon the tape for frequent reference, a *clip* (made by bending sharply upon itself a piece of steel ⅛ in.×3 in.) is slipped upon the tape, where it will remain unless subject to considerable force.

What are known as *metallic tapes*, are made in lengths of 25, 50, and 100 ft., and are graduated in hundredths of a foot for surveyors and into inches and eighths for mine foremen. These are similar to the 100-ft. steel tape but are made of linen, with threads of copper woven in to overcome the tendency to stretch. One of these tapes, 100 ft. long, is part of every surveying outfit and it should be used, wherever possible, to save the more costly 100-ft. steel tape. The metallic tape answers every purpose in measuring the dimensions of buildings that must appear on the map, the width of small streams, roads, etc., and the distance to a property corner, if it is a nearby tree or other not sharply defined point.

*Pins* are now but little used except in those classes of work where the use of the chain is permissible. Pins should be from 15 to 18 in. long, made of tempered-steel wire, and should be pointed at one end, and turned with a ring for a handle. When using a 50-ft. chain, a set of pins should consist of eleven, one of which should be distinguished by some peculiar mark. This should be the last pin stuck by the front chainman. When all eleven pins have been stuck, the front chainman calls "Out!" and the back chainman comes forwards and delivers him the ten pins that he has picked up, and he notes the out.

When giving the distance to the transitman, he counts his outs, each of which consists of 500 ft., and adds to their sum the number of fifties as denoted by the pins in his possession, and the odd number of feet and fractional parts of a foot from the last pin to the front end of the chain. Pins cannot be used in underground work as they cannot be stuck in the floor. If the distance to be measured is longer than the tape, a tack is placed in a tie between the stations and a measurement taken to it from each station with the dip of the sights. In outside work, a stake with a tack is used for the same purpose, and is lined in with the transit.

The *clinometer*, or *slope level*, is a valuable instrument for side-note work; but it is not accurate enough for a survey, and its place is taken by the vertical circle on the transit. There are two styles of clinometer, with a bubble and with a pendulum. The latter is the old-fashioned and more accurate German *gradbogen* that is used by some old corps. The bubble variety is much more easily rendered worthless by the breaking of the bubble tube, and, in general, is not so accurate as the other style, which consists of a semicircular protractor cut out of thin brass and furnished with hooks at each end, that it can be hung on a stretched string so that the string will pass through the 0° and 180° points. The dip is read by a pendulum swung from the center of the circle. If made sufficiently large, it will readily read to quarter degrees. By inclining the string parallel to the surface and hanging the clinometer, the dip will be obtained. A pocket instrument combining a compass and clinometer can be obtained from any dealer in surveying instruments.

# TRANSIT SURVEYING

## READING ANGLES

The angle read may be included or deflected. If the transit is set up at 0, and a backsight taken on *B* and a foresight taken on *C*, it will be noted that there are two angles made by the line *CO* with the line *BOA*, namely the included angle *BOC*, and the deflected angle *AOC*. It will be further noted that *AOC* = 180° − *BOC*, and vice versa.

**Reading the Included Angle.**—To read the included angle, set the zeros of the vernier and the limb as near together as possible by the eye, clamp the upper plate and bring the zeros into exact coincidence by means of the upper tangent screw. Set the vertical hair approximately upon the backsight, clamp the lower motion, and by the lower tangent screw, make the setting exact. Loosen the upper clamp, set approximately on the foresight, tighten the upper clamp, and by means of the upper tangent screw make the setting exactly. The vernier will read, say 45°, which is the included angle *BOC*.

**Reading the Deflected Angle.**—After arranging the verniers as just explained, to read the deflected angle, invert the telescope so that the level bubble is above, and set upon the backsight as before. Turn the telescope back to its normal position (this is called *plunging* the telescope) and sight to the foresight as explained. The vernier will read a right angle of 135°. As noted, the sum of the included and deflected angles must always be 180°, and in the case given 45° +135° = 180°.

## MAKING A SURVEY WITH A TRANSIT

**Meridians, or Base Lines.**—Every survey must start from some fixed point and the angles measured in the course thereof must be referred to some line as a base. The nature of the base line depends on the use to which the survey of the property is to be put. When surveying small tracts of land, such as city or town lots, the starting point may be a stake driven into the ground or a corner of the property itself and the base line may be one of the sides of the tract. When surveying farms, it is customary to make one of the property corners the starting point and to use as a base line the magnetic meridian, noting the date on which the survey is made, so that at any subsequent time an allowance may be made for the variation of the needle. When surveying large tracts of land, or even comparatively small ones, upon which mines are to be opened, the starting point is commonly some firmly planted artificial object, and the base line is the true meridian, as determined by astronomical observations on the North Star (Polaris), or on the sun, by methods given under the

head of Latitude and Longitude. The true meridian is the only invariable base line that can always be determined at any time or place by means of the engineer's transit.

**Monuments.**—When establishing a reference meridian or base line for any large coal property, it is not customary to place the monuments marking its extremities exactly in the true north-and-south line; in fact, it is not generally possible to do so. The monuments should be placed where they will not become disturbed by mining operations; where the line of sight between them will not become obstructed by subsequent building operations; and where they will be convenient for use. Hence, monuments should be placed outside the crop line if this comes upon the property so that pillar drawing, followed by settling of the surface, will not throw them out of line. If the property is opened by a shaft, one monument may be placed upon that portion of the surface that will be sustained by the shaft pillar, and the other monument or monuments may be placed upon reservations from under which the coal will not be mined, or may be placed entirely outside the boundaries of the property. If no place that will remain undisturbed during the life of the mine can be found for the second monument, sights may be taken to a number of prominent buildings or natural objects within or without the boundaries of the property. The angles made by the lines joining these objects with the monument as a vertex should be repeatedly read, and the mean of the readings taken as the true angle. Reference points so selected will determine the direction of the meridian at any later date, as it is improbable that all of the five or ten reference points will be disturbed or destroyed.

The cheapest monuments may be made from mine-car axles or from old railroad iron of, say, 60 to 70 lb. to the yd., cut into lengths of from 4 to 8 ft., depending on the nature of the soil. One end should then be sharpened and the axle or rail driven into the ground until about 6 in. project above the surface. A hole is then deeply marked in the top by a center punch and its distance from three or four nearby points is measured. These distances, or *references*, will enable the monument to be found in event of its being subsequently covered with dirt.

Monuments made of rails, unless the ends are driven well below the frost-line, are apt to be moved out of line through the alternate freezing and thawing of the soil; therefore, a better way is to place the monuments in solid, outcropping rock. In this case, a hole some 12 in. deep is drilled in the rock and a bolt of 1-in. or $1\frac{1}{2}$-in. round iron is leaded into it, the head of the bolt being allowed to project 1 or 2 in. above the rock. The bolt is center-punched the same as would be a rail. Sometimes the projecting end of the bolt is threaded so that a cap may be screwed upon it to protect the center. This is a good plan in damp climates if the monument is intended to last many years.

Excellent monuments may be made of dressed stone in which a center-punched bolt is set to mark the exact point. The upper foot, in length, of the stone, about 6 in. of which projects above the surface, is dressed square with a side of 6 to 8 in. The lower portion beneath the ground should be as large, and consequently as heavy, as possible. The length should be 4 ft. or more, so that the bottom is set well below the frost line. Concrete monuments are cheaper than stone and may be constructed of any size. They are, of course, built up in a pit of good depth, the center bolt being placed before the cement has had time to set.

The boundary of a large property may be 5, 10, or more mi. in length. As it is impossible to tell, in advance, when and where new property will be acquired, necessitating an extension of the original survey, it is a most excellent plan to set a pair of monuments at intervals of about 1 mi. along the line of the survey. The wooden pegs used as stations in the original survey, will disappear in 12 to 18 mo. or will have been so displaced by the action of frost as to be useless. If two consecutive stations are made of rails placed in the fashion of monuments, they will serve at any future time as a base for the extension of the survey. These *permanent stations*, as they are frequently called, should be carefully witnessed and referenced.

## OUTSIDE SURVEYS

**Preliminary Work.**—Before the survey of a property is undertaken, it is highly advisable that the surveyor should go over the ground and familiarize himself with the location of all the corners, roads, streams, houses, outcrops, reservations, and other features that are to appear upon the map. While in some cases a map of the property is furnished the surveyor, it is usually necessary for him to prepare one from the deeds to its component tracts as recorded

at the county seat. A large property is usually made up of from 10 to 100 or more tracts varying in size from a fraction of 1 A. to 100 A. or more. As the surveys found in the deeds were made at widely different dates, the bearing of a line common to two or more properties is commonly different in each deed in which it is mentioned. In such cases, the surveyor should mark on his tracing the different bearings given, as well as the different lengths for each line. With this map, a good pocket compass, and a 100-ft. tape, together with what information may be picked up from residents along the line, the surveyor and his assistant can locate and mark the various corners.

**Angular Measurements.**— The angular measurements in a survey may be made by one of two methods. In one, the angle at any station is read but once, the method commonly used being known as the *continuous vernier;* in the other method, the angle at each station is read twice. By the first method, no check on the accuracy of the work is afforded until the initial station of the survey is occupied with the transit and the azimuth of the first line redetermined, affording what is known as a *close.* As the bulk of the time in the field is employed in setting up the transit, it would seem but ordinary good sense to repeat or check the angles at each station that the accuracy of the work may be certain as the survey proceeds. In no case should the results of a single-angle survey be accepted as correct until such a close has been made.

When making a survey by single angles, the procedure is as follows: Set the transit over the monument marking one end of the base line, which is called Sta. 0. Assuming that the base line makes an angle of 48° 21′ to the right of the meridian, this angle is the azimuth of the base line; and as it is to right of the meridian, its bearing is N 48° 21′ E. Set off this azimuth on the limb of the transit and focus the vertical hair on the second mounment; the line of collimation of the transit will now be in a line directed N 48° 21′ E, and if the upper plate is loosened and the instrument set on any distant object, the azimuth and bearing of that point from Sta. 0, may be read from the graduated limb. Suppose the sight is taken to Sta. 1 of the survey. If the reading on one set of graduations is 326° 48′, which is the azimuth of the line 0–1, the reading on the other set will be N 33° 12′ W, which is the bearing of the line 0–1.

Setting up the instrument over Sta. 1, the vernier is read, to see that it still reads 326° 48′. Then invert the telescope so that the level tube is on top, and by means of the lower motion, take a backsight on Sta. 1. When the telescope is plunged into its normal position (level tube below), the line of sight is in the line 0–1 produced with an azimuth of 326° 48′. Loosen the upper motion and sight on Sta. 2 of the survey. If the azimuth from one set of graduations is, say, 266° 10′, the bearing from the other set will be S 86° 10′ W. Continue this work from station to station until the transit finally reoccupies Sta. 0, the monument at one end of the base line. If, now, the azimuth of the base line as determined by reference to the last line of the survey is found to be 48° 21′ as determined astronomically, all of the angles of the survey have been measured correctly, and the survey is said to *close in angle.*

When making a survey by double angles at each station, assume that the azimuths of the lines are the same as those just used for illustration and that the transit is set up at Sta. 1. Set the vernier at 0° and take a backsight on Sta. 0. If the upper motion is loosened and the telescope revolved 180° around its vertical axis, the line of sight will be in the line 0–1 produced. Continue revolving the telescope until it is set upon Sta. 2, when it will have been turned to the left of the line 1–0 produced and the angle made by the line 1–2 with this line (0–1 produced) is a deflection angle to the left, or a *left angle* commonly called. This will be found to be (in the assumed case) 60° 38′. Next, set the vernier on the azimuth of the line 0–1, viz.: 326° 48′ (bearing N 33° 12′ W), and with the telescope inverted take a backsight upon Sta. 0. Plunge the telescope and by the upper motion set on Sta. 2. The azimuth will be found to be 266° 10′ (bearing S 86° 10′ W). As the deflection angle subtracted from the azimuth of the line 0–1 gives the azimuth of the line 1–2, the angles have been correctly read. Thus 326° 48′ (azimuth) − 60° 38′ (deflection angle) = 266° 10′ (azimuth line 1–2). Similarly N 33° 12′ W (bearing line 0–1) + 60° 38′ (left deflection angle) = N 93° 50′ W = S 86° 10′ W (bearing of line 1–2).

It is customary to read and record the deflection angle first, and then to read and record the azimuth or bearing. After the main angles by which the survey is continued have been noted, before moving to the next station, all the corners, houses, roads, streams, etc., that can conveniently be reached from the instrument should be located and entered in the notebook.

Whether the direction of a line of a survey shall be recorded and described by its azimuth or by its bearing is a matter of choice. Few of those for whom the map is chiefly made are familiar with the former term, and the statement that a certain property line or heading has an azimuth of, say, 286° 10′ does not give them any idea as to its direction; whereas, every layman understands the meaning of the equivalent bearing, S 86° 10′ W. For this reason it seems better to give the bearings of lines instead of their azimuths.

**Distance Measurements.**—A general rule that should not be broken is that all operations necessary to carry on the main line of the survey must be done before anything else is attempted. Therefore, after reading and recording the angle between the lines of the survey, and checking it by the method just explained, the distance to the next, or foresight, station must be read. The method of doing this will depend on whether a 100-ft. tape or chain is used, or, as is the better practice, a 400-ft. tape is employed.

The method of using a chain on level ground has been described. On ground sloping, say, down hill from the instrument, one end of the chain is held at the tack in the stake marking the station, and as much of the tape as can be held horizontal is stretched out in the line to the next station. The end of the horizontal portion of the chain is marked on the ground by dropping a plumb-line from it. The length of this level portion is noted on a piece of paper; the end of the tape held at the plumb-bob in the ground and another length of level tape stretched out and its end marked, and length noted as before. This is kept up until the distance between the stations has been covered, when the sum of the single measurements, is equal to the entire measurement. This is a slow, laborious, and generally inaccurate method that has, by mine surveyors, at least, given way to the use of the long steel tape.

If the distance between stations is less than the length of the tape and the ground is level or uniformly sloping, the 0 end of the tape is held at the tack in the stake at the instrument and the distance to the tack in the foresight stake read, as previously explained. If the ground slopes either up or down hill, the angle of elevation or depression of the slope must be taken and recorded as a plus (+) angle if one of elevation, or as a minus (−) angle, if one of depression. If the tape has been stretched along a plane surface, as explained, the line of sight when the so-called vertical angle is read must be parallel to the tape. To do this, a sight must be taken at a point on the foresight rod as far above the ground as is the center of the telescope axis at the instrument station. If the ground is not uniformly sloping, the 0 end of the tape is held at the hole marking the end of the horizontal axis of the telescope, and the measurement is made to the tack in the foresight stake. In this case the vertical angle is measured directly, exactly as the horizontal cross-hair cuts the station tack.

Distance on slope × cos vertical angle = horizontal distance          (1)

Distance on slope × sin vertical angle = difference in elevation      (2)

The reduction of the slope distances to horizontal ones is made in the office, not in the field. If the elevation of the first survey station is known, that of all the other stations is obtained by adding continuously to it the difference in elevation, as obtained from formula 2. While elevations thus obtained are not so accurate as those secured through the use of leveling instruments, they answer every purpose as a basis for a topographical survey made with the stadia.

If the distance is greater than the length of the tape, but less than twice as great, say 790 ft., a stake with a tack is placed about half way between the stations and in the line joining them. The distance and vertical angle to the stake are read after making the foresight, and again from the next station, after taking the backsight. The sum of these distances, after reduction to the horizontal, is the total distance between the two stations.

If the distance is greater than two tape lengths, say, 1,000 ft., two stakes must be set. The first stake *a* may be placed, say, 350 ft. from the instrument, and the second stake *b*, 350 ft. beyond that. Before moving the transit the distance and vertical angle to *a* must be read and the transit set up roughly over *a* and the distance and vertical angle to *b* read. At the next station and on the backsight, the distance and vertical angle to *b* must be read. The sum of these three distances reduced to the horizontal is the distance between the stations.

**Locating Corners, Etc.**—After the main-line angle is read and checked and the distance to the next station measured (or such part of it as is possible without moving the transit) a sight or sights should be taken to any nearby property corner or corners and the azimuth or bearing, as well as the distance and the vertical angle thereto recorded. It should be noted that the deflection

angle between the lines joining stations should be read first, as the instrument must be properly oriented before corners, etc., can be located, and this orientation is secured at each station by using as a backsight for the second reading, the azimuth of the line joining the backsight and instrument stations as determined from the previous set-up. After the corners have been located, stadia sights are taken to any houses, streams, roads, topographic features, etc., that should appear upon the map.

**Keeping Notes.**—The various ways of keeping the main-line and side notes of an outside survey arrange themselves into four groups: (1) The side notes of each sight follow the transit notes of that sight, and on the same page. (2) They are entered in the same book on opposite pages. (3) The transit notes of the whole survey come first, and are followed by the side notes in the same book. (4) Each set of notes has a separate book.

Of these notes, the second and third are in common use. For a survey made by the methods just explained, the accompanying form of transit notes is the usual one. The columns are headed for station (Sta.), Bearing, Angle (deflection angle) which may be either R (right) or L (left), distance (Dist.), and Slope (vertical angle, or pitch).

TRANSIT NOTES

| Sta. | Bearing | Angle | | Dist. | Slope |
|------|---------|-------|------|-------|-------|
| | | R | L | | |
| $M_1-M_2$ | N 48.21 E | (Bea | ring of base | line) | |
| $M_1-1$ | S 26.30 W | | 21.51 | 262.83 | −4.16 |
| $1-2$ | S 67.49 W | 41.19 | | 387.62 | −2.18 |
| $2-3$ | N 86.11 W | 26.00 | | 316.99 | +0.16 |
| $3-4$ | S 55.28 W | | 38.21 | 365.34 | +1.56 |

The bearing of the base line, or that joining the two monuments, $M_1$ and $M_2$, is N 48.21 E. It will be noted that the signs ° and ′ are not used, a period serving to separate the degrees and minutes. This saves time. The notes are simple and self-explanatory. The transit is always assumed to be at the station whose number or letter is given first in the station column. Thus, the instrument is at Sta. $M_1$, 1, 2, and 3. The foresight follows the instrument station in the same horizontal line. Thus, the foresights to Sta. 1, 2, 3, and 4, are made from Sta. $M_1$, 1, 2, and 3, respectively. The backsight at Sta. 1 is, of course, $M_1$, at Sta. 2, it is 1, and similarly. It should be noted at Sta. $M_1$, when the vernier is set for the purpose of taking the azimuth or bearing of the line 1–2, that the setting S 48.21 W and not N 48.21 E is used. This is because the line $M_2-M_1$ runs in exactly the opposite direction from the line $M_1-M_2$, and the survey is moving forwards in the former line.

As stated, the side notes are entered in the same book as the main-line notes, but usually in the back. It is well to head a certain page, say, Sta. 1, and then to follow with all the side notes taken at that station, and similarly for the succeeding stations. The condition of all property corners should be carefully described, as their present state is often very different from what it was at the time the original deeds were made. Thus, a corner described as a hemlock sapling in a deed dated 1790, may now be a tree 2 or 3 ft. in diameter, may be a stump, may have entirely rotted away so that only an expert can tell from the decayed remains that a hemlock once marked the corner, or a good-sized oak, sugar maple, or hickory may have replaced it, the hemlock having been destroyed but a few years after the deed was made and a tree of another species grown in its place.

Frequently there are reservations around farm houses from under which the coal may not be mined. Sometimes the corners of these *reserves* (as they are often called) can be reached in a single sight; if not, a branch line must be run to them from the line of the main survey.

When locating houses by stadia sights, two men are necessary. One can hold the stadia rod at the opposite corners of the house, but a second is required to hold the tape by which the dimensions of the buildings are secured. Roads are located by the fences on either side, the road legally occupying all the space between the fences, even if part of it is grown up in weeds and the wagons

have made but a single line of ruts. Roads are commonly either 1 or 2 rd., that is, 16.5 or 33 ft. in width, and should be so mapped.

Small brooks are located by taking a stadia sight to their center at each important bend. Larger creeks should have one bank located with the stadia, the stadia rodman estimating the width of the stream, which should be entered in the notes. Large rivers should have a regular traverse run along the bank, the opposite side being located by stadia sights. In the case of very large rivers, a transit line must be run along each bank and the shore line located by stadia sights. Stadia sights should be taken to points along the bottoms of all dry gulleys, to the summits of all ridges, and to any marked change in the degree of slope of a hill.

If the vertical angles have been taken when the distances between the stations were measured and the stadia sights taken as just explained, there will be gathered in the course of the survey enough data to make a very complete topographic, or contour, map of the property. This will particularly be true, if, as is customary, the boundaries of the individual farms making up the entire property are surveyed. The reason for surveying the single farms is that very frequently the operating coal company has not the same rights in all of them, so that the method of mining is affected by what the company can and cannot do.

The kind, dip, and strike of all outcropping ledges or other exposures of rock should be noted and mapped. The information thus obtained, combined with the elevations obtained with the stadia, etc., furnishes the data from which geological cross-sections may be made.

The first page of the notebook should give the name of the company for whom the work is done, the location of the property, name of the engineer in charge of the work, the names of the helpers, and each day's work should be dated; and if the members of the corps have changed, this, too, should be a matter of record.

If more than one property is being surveyed from the same office, a separate set of field books should be devoted to each. It is an excellent plan at night to copy at least the main-line notes in a permanent notebook, which is left at the office, or at the farmhouse if the corps is in the field. Sometimes the side notes are also copied. These copies are made so that all the records may not be destroyed, necessitating an entirely new survey, should anything serious happen to the field book. When not in use, all field books, both originals and copies, should be kept in a fireproof vault.

**Closing Surveys.**—To diminish the chance of error, even if double angles have been read, the survey must be closed upon itself or some part of a former closed survey. That is, the transit must a second time occupy the initial station, so that the first azimuth read may be referred back to the last line of the survey. If the azimuth (or bearing) as read the second time agrees with that obtained at the first reading, the angular readings are proved to have been correctly made. If the error in closure is not more than 1' to 3' in a line 4 or 5 mi. in length, most surveyors will balance the survey, but in important work the error must (or should) be located so that the survey will close exactly *in angle.* Usually one or more stations will be selected as the most probable ones at which the error (all or in part) was made. These stations will be those at which good sights were not to be had owing, say, to smoke obscuring the point of the plumb-bob underground or, in the case of surface surveys, to the station stake on either backsight or foresight being beyond a roll in the ground so that the tack or the point of the rod was not visible. These doubtful stations may be reoccupied and the angles remeasured with special care. If not located at the probable places of error, the survey, so far as the angle measurements are concerned, may be rerun in its entirety; but this is rarely necessary. If the angles cannot be made to close upon resurvey, the failure to do so is probably caused by cumulative errors, a few seconds at each station. These errors are, singly, too small to measure, but in a survey of 40 or 50 stations may amount to 1' or more. Errors in linear measurement are far more common than errors in angular measurement, as there is no field check upon the work with the tape unless the distances are read twice, on the foresight from the one station and on the backsight from the next. A wrong reading of the vertical angle will, of course, affect the horizontal distance. Errors in measurement are often of 5 or 10 ft. due to incorrectly reading the graduations on the tape. Perfect linear measurements are far more difficult to make than perfect angular measurements. This is because the correct length of a line is very materially affected by variations in the length of the tape due to the effects of sag, tension, changes in temperature, etc. In highly accurate work, corrections should be made for all of these.

The allowable error in closure depends on many things, the chief of which is financial. If it will cost more to locate and correct the error than the value of the land saved, it will not pay to do so. In other words, far more time (consequently, money) may be spent upon a survey of coal land worth $2,500 an A. than upon land costing but $5 an A. In ordinary rolling country, such as prevails in the coal fields of the eastern states, with instruments in good adjustment and using ordinary precautions, the error in closure should not be greater than 1 ft. in 3,000 ft. to 1 ft. in 5,000 ft., and trained corps will do better. In bituminous mines, which are commonly in flat coal, underground surveys may easily be closed within 1 ft. in 10,000 ft. to 1 ft. in 20,000 ft. The higher accuracy obtainable underground is due chiefly to the fact that mine temperatures are extremely uniform so that corrections for expansion or contraction of the tape are unnecessary. Likewise, the tape is stretched on the ground and errors due to sag are thus eliminated.

---

# LEVELING

## DESCRIPTION OF INSTRUMENTS

In *leveling*, but two instruments are used, the level and a leveling rod. The *level* consists of a telescope to which is fitted, on the under side, a long level tube. The telescope rests in a **Y** at each end of a revolving bar, which is attached to a tripod head very similar to that used for a transit. The telescope is similar to the telescope of a transit.

The *leveling rod* is merely a straight bar of wood, 6 ft. or more in length, divided into feet and tenths of a foot. A target divided into four equal parts by two lines, one parallel with the staff, and the other at right angles to it, and painted red and white, so as to make it prominent at a distance, slides on the rod and is provided with a clamp screw. The center of the target is cut out and a vernier, graduated decimally, is set in, which enables the rodman to read as close as $\frac{1}{1000}$ ft. If a long rod is required, it is made of two sliding bars, which, when closed, are similar to a single rod, as described above. When used at points where it is necessary to shove the target to a greater height than 6 or $6\frac{1}{2}$ ft., the target is clamped at the highest graduation on the front of the rod, and the rod is extended by pushing up the back part, which carries the target with it. The readings, in this case, are made either from the vernier on a graduated side, or a vernier on the back. The rodman must always hold his rod perfectly plumb or perpendicular.

## LEVEL ADJUSTMENTS

The proper care and adjustment of the level is of great importance. A very slight error in adjustment will completely destroy the utility of any work done.

1. *To Adjust the Line of Collimation.*—Set the tripod firmly, remove the **Y** pins from the clips, so as to allow the telescope to turn freely, clamp the instrument to the tripod head, and, by the leveling and tangent screws, bring either of the wires upon a clearly marked edge of some object, distant from 100 ft. to 500 ft. Then with the hand, carefully turn the telescope half way around, so that the same wire is compared with the object assumed. Should it be found above or below, bring it half way back by moving the capstan-headed screws at right angles to it, remembering, always, the inverting property of the eyepiece; now bring the wire again upon the object, and repeat the first operation until it will reverse correctly. Proceed in the same manner with the other wire until the adjustment is completed. Should both wires be much out, it will be well to bring them nearly correct before either is separately adjusted.

2. *To Adjust the Level Bubble.*—Clamp the instrument over either pair of leveling screws, and bring the bubble into the center of the tube. Now turn the telescope in the wyes, so as to bring the level tube on either side of the center of the bar. Should the bubble run to the end, it shows that the vertical plane, passing through the center of the bubble, is not parallel to that drawn through the axis of the telescope rings. To rectify the error, bring it by estimation half way back, with the capstan-headed screws, which are set in either side of the level holder, placed usually at the object end of the tube. Again bring the level tube over the center of the bar, and adjust the bubble in the center, turn the level to either side, and, if necessary, repeat the correction until the bubble will keep its position, when the tube is turned $\frac{1}{2}$ in. or more to either side of the center of the bar. The necessity for this operation arises from the fact that when the telescope is reversed, end for end, in the wyes in the other and principal adjustment of the bubble, it is not easy to place the

level tube in the same vertical plane, and, therefore, it is almost impossible to effect the adjustment without a lateral correction.

Having now, in a great measure, removed the preparatory difficulties, it is possible to proceed to make the level tube parallel with the bearings of the Y rings. To do this, bring the bubble into the center with the leveling screws, and then, without jarring the instrument, take the telescope out of the wyes and reverse it end for end. Should the bubble run to either end, lower that end, or what is equivalent, raise the other by turning the small adjusting nuts, on one end of the level, until, by estimation, half the correction is made; again bring the bubble into the center and repeat the whole operation, until the reversion can be made without causing any change in the bubble. It is well to test the lateral adjustment, and make such correction as may be necessary in that, before the horizontal adjustment is entirely completed.

3. To Adjust the Wyes.—To adjust the wyes, or, more precisely, to bring the level into a position at right angles to the vertical axis, so that the bubble will remain in the center during an entire revolution of the instrument, bring the level tube directly over the center of the bar, and clamp the telescope firmly in the wyes. Place it, as before, over two of the leveling screws, unclamp the socket, level the bubble, and turn the instrument half way around, so that the level bar may occupy the same position with respect to the leveling screws beneath. Should the bubble run to either end, bring it half way back by the Y nuts on either end of the bar; now move the telescope over the other set of leveling screws, bring the bubble again into the center, and proceed precisely as just described, changing to each pair of screws, successively, until the adjustment is very nearly perfected, when it may be completed over a single pair.

The object of this approximate adjustment is to bring the upper parallel plate of the tripod head into a position as nearly horizontal as possible, in order that no essential error may arise, in case the level, when reversed, is not brought precisely to its former situation. When the level has been thus completely adjusted, if the instrument is properly made and the sockets are well fitted to one another and the tripod head, the bubble will reverse over each pair of screws in any position. Should the engineer be unable to make it perform correctly, he should examine the outside socket carefully, to see that it sets securely in the main socket, and also notice that the clamp does not bear upon the ring that it encircles. When these are correct, and the error is still manifested, it will probably be in the imperfection of the interior spindle.

After the adjustments of the level have been effected and the bubble remains in the center in any position of the socket, the engineer should carefully turn the telescope in the wyes, and sighting upon the end of the level, which has the horizontal adjustment along each side of the wye, make the tube as nearly vertical as possible. When this has been secured, he may observe, through the telescope, the vertical edge of a building, noticing if the vertical hair is parallel to it; if not, he should loosen two of the cross-wire screws at right angles to each other, and with the hand on these, turn the ring inside, until the hair is made vertical; the line of collimation must then be corrected again, and the adjustments of the level will be complete.

## USING THE LEVEL

When the instrument is being used, its legs must be set firmly into the ground, and neither the hands nor person of the operator be allowed to touch them. The bubble should then be brought over each pair of leveling screws successively, and the instrument leveled in each position, any correction being made in the adjustments that may appear necessary. Care should be taken to bring the wires precisely in focus, and the object distinctly in view, so that all errors of parallax may be avoided.

An error of parallax is seen when the eye of an observer is moved to either side of the center of the eyepiece of a telescope, in which the foci of the object and eyeglasses are not brought precisely upon the cross-wires and object; in such a case, the wires will appear to move over the surface and the observation will be liable to inaccuracy. In all instances, the wires and object should be brought into view so perfectly that the spider lines will appear to be fastened to the surface, and will remain in that position however the eye is moved.

If the socket of the instrument becomes so firmly set in the tripod head as to be difficult of removal in the ordinary way, the engineer should place the palm of the hand under the Y nuts at each end of the bar, and give a sudden upward shock to the bar, taking care, also, to hold his hands so as to grasp it the moment it is free.

## FIELD WORK

If the survey has been carefully made and vertical angles taken at every sight, leveling will be necessary only in cases where extreme accuracy in regard to vertical heights is necessary. In most cases of practical work at collieries, particularly in determining thickness of strata, general rise or fall of an inside road, etc., the elevations calculated by the use of the vertical angle will be close enough, but there are frequently instances when leveling must be done, to insure success in certain work. In this connection, it is well to state that if the transit telescope is supplied with a long level tube, and it is, as a whole, in first-class adjustment, levels can be successfully run with it if the transitman uses due care. Having his instrument in proper adjustment and his notebook ruled, the levelman is ready to proceed with the work.

The rodman holds the rod on the starting point, the elevation of which is either known or assumed. The levelman sets up his instrument somewhere in the direction in which he is going, but not necessarily, or usually, in the precise line. He then sights to the rod and notes the reading as a backsight or + (plus) sight, entering it in the proper column of his notebook, and adding it to the elevation of the starting point as the "height of instrument." The rodman then goes ahead about the same distance, sets his rod on some well-defined and solid point, and the levelman sights again to the target, which the rodman moves up or down the rod until it is exactly bisected by the horizontal cross-hair in the telescope, as he did when giving the backsight. This reading is noted as a foresight or − (minus) sight. The foresight subtracted from the height of instrument gives the elevation of the second station. The rodman holds this latter point, and the levelman goes ahead any convenient distance, backsights to the rod, and proceeds as before. In this case, it is assumed that levels are only being taken between regular stations or two extreme points.

If a number of points in close proximity to each other are to be taken, the rodman, after giving the backsight, holds his rod at each point desired. The readings of any number in convenient sighting distance are taken and recorded as foresights, and any descriptive notes are made in the column of remarks. These are each subtracted from the height of instrument, and the elevation found is noted in column headed Elevation. After all the intermediate points are taken, the rodman goes ahead to some well-defined point, which is called a turning point (T. P.) in the notes. The elevation of this is found and recorded. The rodman remains at this point until the levelman goes ahead, sets up and takes a backsight. This backsight reading, added to the elevation of the turning point, gives a new height of instrument from which to subtract new foresights, and thus obtain the elevation of the next set of points sighted to.

When running levels over a long line, the levelman should set frequent *bench marks* (B. M.). These are any permanent well-defined marks that can be readily found and identified at any future time. By leveling to them he has secured the elevation of points from which to start any subsequent levels that may be necessary. A good bench mark can always be made on the side or root of a large tree or stump by chopping it away so as to leave a wedge-shaped projection with the point up. A nail should be driven in the highest point of this, to mark where the rod was held, and the tree or stump blazed

LEVEL NOTES

| Station | B. S. | F. S. | H. Inst. | Elev. | Remarks |
|---|---|---|---|---|---|
| 1 | 3.412 | | 103.412 | 100. | Assumed elevation of Sta. 1. |
| 2 | | 4.082 | | 99.33 | Sta. 2 of survey. See page—— Vol.—— |
| | | 6.791 | | 96.621 | Sight taken to ground at N. E. cor. John Smith's house. |
| 3 = T. P. | 11.698 | 4.862 | 110.248 | 98.55 | Sta. 3 of survey noted above. |
| 4 | | 9.817 | | 100.431 | Sta. 4 of survey noted above. |
| B. M. 1 | | 6.311 | | 103.937 | B. M. 1 is on north side of large white oak. |
| 5 | | 6.427 | | 103.821 | Sta. 5 of survey noted above. |

above the bench mark. In this blaze, the number of the bench mark, which should, of course, correspond with the number in the notebook, should be cut or painted. In the mines, prominent frogs or castings in the main roads, if permanent, make good bench marks.

In underground leveling, extreme care must be observed to record the algebraic signs of the readings, which show whether the level rod was held in its usual position, indicated by a + sign or the absence of any sign, or upside down, indicated by the − sign.

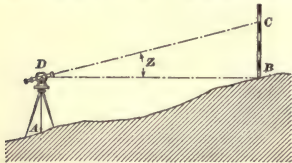
**Proof of Calculations.**— The calculations are proved by adding together the backsights and also the foresights taken to turning points and last station. Their difference equals the difference of level between the starting point and last station. Thus:

| Foresights | Backsights |
|---|---|
| 4.862 | 3.412 |
| 6.427 | 11.698 |
| 11.289 | 15.110 |
| | 11.289 |
| | $3.821 = 103.821 - 100.0$ or $3.821$ |

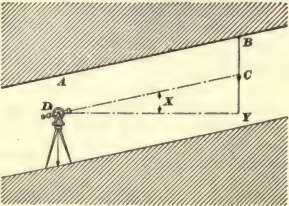
## TRIGONOMETRIC LEVELING

*Trigonometric leveling* determines the difference in elevation between two points from the measurement of the distance between the points, and from the vertical angle between them. Although generally less accurate than leveling with a **Y** level, it is much more rapid and is especially adapted for pre-

FIG. 1

liminary work in a hilly country, or for the leveling of mine slopes or pitching rooms where the **Y** level cannot be used with any advantage or accuracy. By reading the angles and by checking the measurements, a very high degree of accuracy can be obtained in trigonometric leveling.


**Case 1.**—Assume the elevation of $A$, Fig. 1, to be 100 ft. above tide. With the transit set up over $A$ and properly leveled, sight to a point $C$ on a rod so that $BC$ equals $AD$. Measure the vertical angle $Z$ and the inclined distance $DC$, then the difference in the elevation between $A$ and $B$ equals $BC = CD \times \sin Z$, and the elevation of $B$ equals $100 + BC$.

**Case 2.**—Assume the elevation of station $A$, Fig. 2, in the roof of a mine to be 100 ft. above tide. Then, with the transit set up directly under $A$ and properly leveled sight to a point $C$ upon the plumb-line suspended from the station $B$, measure the vertical angle $X$, inclined distance $DC$, and roof distance $BC$. From this, the distance $CY = DC \times \sin X$. The elevation of $B$ is then found as follows: The elevation of $B$ = elevation of $A - AD + (DC \times \sin X) + BC$.


There are many modifications of this simple method, but from these diagrams the most complex modifications can be worked out.

FIG. 2

### TRIGONOMETRIC LEVEL NOTES

| Station | Vertical Angle Degrees | Inclined Distance | Vertical Distance | Height of Instrument Feet | Roof Distance Feet | Elevation Feet |
|---|---|---|---|---|---|---|
| $A$ | | | | | | +100.00 |
| $A - B$ | +5 | 100 | +8.72 | 2 | 3 | 109.72 |
| $B - C$ | +2 | 100 | +3.49 | 3 | 2 | 112.21 |
| $C - D$ | −3 | 100 | −5.23 | 4 | 3 | 105.98 |
| $D - E$ | −4 | 100 | −6.98 | 2 | 1 | 98.00 |

# CONNECTING OUTSIDE AND INSIDE WORK THROUGH SHAFTS AND SLOPES

## SURVEYING SHAFTS

As the dip of the bed increases, it becomes more difficult to make a connection and the chances of accuracy diminish. In the survey of a pitching plane, one station is located, with respect to the adjacent ones, by multiplying the distance by the cosine of the vertical angle. The greatest angular accuracy for a given distance is where the vertical angle is 0°. As the pitch or vertical angle of sight increases the cosine diminishes until, at a vertical sight, distance × cos. vertical angle = 0°.

In the case of an adit level, or a slope of less than 45°, there is no difficulty beyond the want of absolute rigidity in setting up the transit, and the danger of moving it in going about it. The difficulty increases more rapidly than does the pitch, and as the distance × cos. vertical angle diminishes, though the distance is fixed, the chances of error increase. When the slope reaches 60°, there is an impracticability in running a line down a slope, as the line of collimation of the telescope strikes the graduated limb of the instrument. A person can use a prismatic eyepiece and see up the slope; but cannot look down. As it is assumed that it is unnecessary to use an additional telescope, the line must be run by intermediates. To do this, the transit should be set up at the bottom of the slope where the longest sight up the same can be secured and a backsight taken on a station of the underground work; or a backsight should be set for the occasion (both stations will afterwards be connected with the work below). With the prismatic eyepiece, a sight should be taken up the slope on a line that will give the longest sight and, at the same time, afford a good intermediate place to set up the transit, as, on a pitch of 60° or more, it is absolutely necessary that the legs of the transit should be set solidly (in holes in the floor, or between the sills of the track) so that they will not be moved by subsequent walking about it. By this method, all the sights will be taken from one side alone, and the tripod legs can be shortened to make the sight possible without building a standing place—if the man is short.

Call this station $A$; at the foot of the slope locate $B$, where the transit can be readily set up, and as far up the slope as possible (this distance must be at least 100 ft.), and in a continuation of $AB$, locate $C$. Set up at $B$ and take foresight to $C$; locate $D$ under the same conditions that governed the placing of $B$, and, in a continuation of the line $BD$, place $E$. Set up at $D$ with foresight at $E$, and locate $F$ and $G$ as before. The survey is carried by the intermediates $B$, $D$, $F$, etc., to the top, by a series of foresights to $C$, $E$, $G$, etc.

The term *shaft* in American coal-mining practice is applied only to vertical openings, though in metal mining, both in the United States and abroad, it is also applied to highly inclined slopes. For such shafts, most of the methods given in the textbooks are worthless, as they are for transit work and the distance × cos. vertical angle in rare cases may be as great as 20 ft., while the distance varies from 100 to 1,500 ft. Again, to sight down a shaft necessitates the erection of a temporary (and therefore more or less unsteady) support for the tripod of the transit, and the chances of variation in its position as the different sights are made are so great that it is difficult to say when a movement has not taken place that will vitiate the work.

In sighting up a shaft of greater depth than 100 ft., there is annoyance—if not danger—from dripping water or the fall of more solid substances. In a wet shaft the object glass is instantly covered with water, and a sight is impossible. Also, it is necessary to stand upon a platform, and it is hard to tell when this is perfectly rigid. From all these considerations the methods with a transit are never used by engineers in the anthracite regions, and the connections are made as follows:

When the bottom of the shaft can be reached by an adit or a slope in a roundabout route of such length as to render errors in measurement of distance of great importance, the angles are carried by a transit with as long sights as possible, and no distances are measured, from a point on the surface in the shaft to a point vertically below it in the mine. Sometimes the guide of the cage is taken when it has been recently set, as the guides are plumbed into position; but the better way is to suspend an iron plummet by a copper wire: sink the former in a barrel of water or bucket of oil so as to lessen the tendency to swing on account of the pull upon the bob and wires from the air-currents, or falling drops in a wet shaft. The top of the barrel should be

covered with two pieces of plank with a semicircular groove of 3 in. radius cut out of the middle for the passage of the wire, to catch the substances whose fall upon the water would cause waves. The heavier the plummet and the lighter the wire, the less the tendency to swing. This wire can be sighted at by parties above and below at the same time, and the swing can be bisected to get the position of the wire. A number of sights that agree can be taken as accurate.

When the shaft is the only way to get below from above, it must be plumbed with two or more wires suspended as just described. When two wires are used, the wires should be so hung that an instrument can be set up below in a line passing through them produced, and at a sufficient distance from them to insure an accurate sight. When more than two wires are used, the underground station can be located at any point at which all the wires can be seen from the instrument.

**Case 1.**—Two wires are used, which are located as far apart as possible. Two pieces of scantling *cd* and *ef*, Fig. 1, are spiked across the opposite corners of two compartments of a shaft to allow the cages to pass up and down without interference. The station *X* is (roughly) located in a line through the corners *x*, and is connected with the outside survey. From this station locate in the line *Xxx* two spads for holding the wires of the plumb-bobs. These are driven up to the head in the scantlings in such a way that the line of sight passes through the center of the holes in their heads. When the distances *Xa* and *ab* are measured, the work of the survey above ground is com-

Fig. 1

pleted. The light copper wire is rolled upon a reel, and one end is fastened to a light plumb-bob to keep it free from coils or kinks in descending. It can thus be readily lowered without accident. When at the bottom, the upper end is fastened in the spad and the heavy bob applied to the bottom and placed in the empty barrel. The cages are then run slowly up and down, with an observer on each, to see that the wires hang free from top to bottom. By this time the wire will have stretched so that it will be straight, all slack is taken up, the barrel filled with water, and the top boards put in place. As a last check, the distance between the wires below is measured, to see if it agrees with the distance above.

Lining in below a point *Y* on the line *ab*, make a hole in the roof 2 in. in diameter, and drive in a broad plug. Setting up the transit under *Y*, sight at the wires *a* and *b* alternately. A number of methods for illuminating the wires have been used. But the most satisfactory method is to place a large white target behind both wires and illuminate them by a large lamp with a reflector behind it. The wire stands out black against the target, and can be followed across it. As there is considerable distance between the wires, and as the transit is comparatively near them, there is little chance of getting a sight of one, when the telescope is focused upon the other, and so the focus has to be set between them. This gives a hazy sight at each; but both are shown against the white background in strong relief. After the transit head is shifted so that the line of sight coincides approximately with both, they should be focused upon alternately so as to see if the line bisects the swing of each. If so, the work is done; if not, the shifting of the transit head must follow until the end is attained. It frequently requires 2 hr. or more of steady observation to complete the work, and, when it seems as if the proper point were secured, one of the wires will show by its swaying that it has been deflected from the vertical by a peculiar slant of wind, and the result obtained must be checked again. When through, there is no absolute certainty that the point marked is in the accurate extension of the line *ab* at the surface. Having decided on the proper place, a spad must be driven into the plug overhead and a plumb-bob hung to it to see if it is over the axis of the transit, as shown by the screw on the telescope. If not, the spad must be driven so that the point of the bob does so hang, and the point *Y* is said to be in the line *ab*. The distance *Ya* and the angles to any station of the underground survey must then be measured and when the line *ab* is connected with the surveys at daylight and below, the plumb-bobs may be removed.

The disadvantages of this method are that there is no absolute certainty that the point *Y* is in the line *ab* prolonged, and this want of certainty should not exist in so important a measurement.

The work must be performed by daylight, and the length of time necessary to complete it makes it impossible to work the shaft for at least ½ da., and may cause annoyance to the operators, or, if you are working for a lessee, lead them to refuse to let you have the use of the shaft at the time most suitable for your purpose.

Underground it may be hard to obtain a long sight on any line running through the larger axis of the shaft. Any shorter line will give too short a base line and will increase the chances of error.

**Case 2.**—Fig. 2 shows the top set of timbers in a shaft of two hoisting compartments, down which it is desired to carry a known course or meridian on the surface to the entry below. It is necessary first, to find out which side of the shaft is best adapted for setting up the transit, as the point to be marked in the mines will be vertically under the point on the surface; consequently, the side with the widest opening leading from the foot of the shaft should be selected.

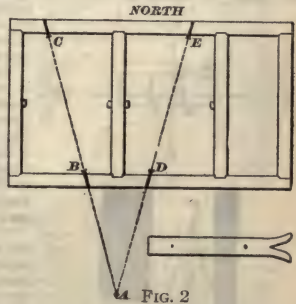
Having carried the meridian to a convenient point near the top of the shaft, and having found that the south side of the shaft is the most accessible, determine, with an ordinary string, the location of the point A, from which the hangers for the plumb-lines will be exactly located, by means of the transit. Now mark with chalk on the timbers where the strings cross. These marks, though not accurate, serve as guides in setting the hangers. Make a permanent station at the point A and carry the meridian to it.

The hangers can be made of strap iron, ½ in. thick by 2 in. wide, and at least 16 in. long. In one end of the iron, have a jaw with a fine cut at the apex, or a drill hole just large enough to contain the wire to be used for plumbing. There should be two or three countersunk holes in the hanger, through which to fasten it to the timbers by means of heavy wire nails. A top view of the hanger is shown in Fig. 2. In most shafts there is a space from 2 to 4 in. wide between the ends of the cage and the sides of the timbers. In order to hoist and lower the

Fig. 2

cage to see that the wires are hanging freely, it is best to set the hangers in such a position on the timbers that the wires will hang in the middle of the space. The hangers should be permanently fastened over the chalk marks previously made on the north side of the shaft, with the jaws pointing toward A, and on the south side of the shaft the outer end of the hanger may be fastened temporarily.

Now, set the transit over the station at A, take the backsight, foresight on the wire hole of the hanger C and set the wire hole of the hanger B on the same line. Record this course and foresight on the wire hole of the hanger E, fixing as before the wire hole of the hanger D in the same line. Record this course, and then the meridian is to be carried into the workings below is established. Measure carefully and record the distances A to B, A to C, B to C, A to D, A to E, D to E, B to D, and C to E, in order to establish a point at the bottom of the shaft vertically below A, and check the work in the office.

The transit party can now descend to the bottom of the shaft, taking with it four buckets of oil, the weights or plumb-bobs to be attached to the wire, and all the surveying instruments, leaving a responsible person on the surface to handle the wires. Having arrived at the bottom of the shaft, the transit-man should have the cage hoisted 3 ft. above the landing, throw several planks across the timbers on which to set the buckets of oil, signal to the man on top to lower a wire and fasten it securely, passing it through the wire hole of the hanger, attach the plumb-bob and adjust the wire to such length that, when sustaining the full weight of the plumb-bob, the latter will not touch the bottom of the bucket. He should then place the weight in the oil, using care not to let the full weight come upon the wire with a jerk, but should let the weight down slowly, so that the wire will receive the full strain gradually. The three remaining wires should be set in a similar way.


After the wires have been hanging a few minutes with the weights attached, the latter may move from one side to the other of the buckets. They should be watched carefully and the buckets moved until all the weights hang perfectly free, then everything should be let alone until the wires become steady. The cages can now be hoisted and lowered for the purpose of examining the wires to see that they hang free and plumb, care being taken that the cages are not brought so close to the landings as to disturb the hangers at the top, or the buckets at the bottom.

To find a point vertically below *A*, a string may be stretched along the wires *B* and *C*, care being taken not to touch them; another may be stretched along the wires *D* and *E*; then, with a plumb-line, a point on the bottom vertically below the intersection of the strings may be determined. The distances *AB*, *AD*, *BD*, and *CE* should then be measured and compared with the corresponding distances at the top of the shaft. If these distances compare favorably, the wires are, in all probability, steady, and the work of determining the desired course with the transit may be begun.

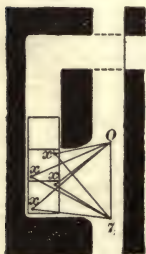
Set the transit up over the point of intersection just found; backsight on the wires *B* and *C*; foresight on the wires *D* and *E*, and compare the included angle and the distances with the corresponding angle and distances at the surface. If these do not correspond, move the transit in the direction necessary to increase or decrease the angle or distances, as the case may be. Repeat this operation until the exact point vertically below *A* is determined.

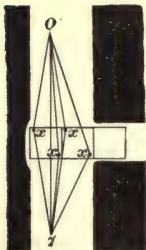
A simple device that is of great advantage is to have three links from an ordinary trace chain placed in the wires on the side toward the transit, and a few feet above the buckets. This not only enables the wires to turn freely, but also enables the transitman to sight through one of the links to the wire beyond, whereby he can place the transit in exact line with the wires more easily than if the links were not there.

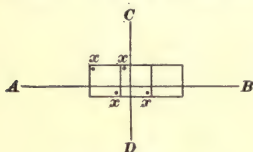
**Case 3.**— Two, three, or four wires may be used, being secured and hung as before. They are located in the angles of the compartments *x*, Fig. 3. These are connected with four stations *A*, *B*, *C*, and *D*, the lines *AB* and *CD* being at right angles to each other for convenience in the subsequent calculation, and are connected with the outside survey. From *A* and *B*, taking *AB* as a base line, the points *x* are located. The same is repeated from *C* and *D*, taking *CD* as a base line. Thus are obtained four locations of each wire; these are tabulated, and any variations in a reading must be followed by a repetition of the same. The mean of the readings gives the location. (Subsequently, the subject of calculating work will be taken up.) It can be briefly stated that the bearings of each wire to each of the others, as referred to the base line of the survey, are then calculated and the distance between the wires accurately measured. This finishes the work at daylight.

There may be two general types of arrangements of the bottom of the shaft, and both arrangements have been sketched and lettered similarly. The first is a case when the shaft is arranged across the dip of the bed, and the second is parallel to the same. In both cases *0* and *7* are taken as far apart as possible, and all the wires *x* are located from each station with reference to the other. The

Fig. 3

distances between the wires above and below are also accurately measured as a check. There will be four locations of *0* and *7* from the four wires,






and the mean of these is taken as the correct one. In every case of angle measurement, a series of readings of each angle is taken on different parts of the graduated limb, to avoid instrumental errors, and the mean of these is taken as the true reading. From the locations of *0* and *7*, the course between them, as referred to the mean base line, is calculated, and *07* is the base line for the underground work. The angle readings above and below can be made at the same time with different instruments, and, in taking the readings below, it is not necessary to wait for absolute quiet in the wires, as that is seldom found. A small swing can be bisected by the cross-hair, and the readings are duplicated until a constant result is secured. By this method a greater accuracy and speed is obtained, and the angles below can be accurately measured, no matter how the shaft may be arranged.

**The T-Square Method.**—The T-square method of taking the line underground is especially valuable in shafts with several small compartments or

in cramped places where one cannot line in with the wires. The wires are placed in separate compartments and as far apart as possible. The apparatus is made by the carpenter, and consists of a straightedge and T squares. The former is merely a planed pine board about 8 in. $\times \frac{3}{4}$ in. and 1 ft. longer than the distance between the wires. It rests approximately horizontally on slats tacked across the shaft for supports. It is brought to about $\frac{1}{8}$ or $\frac{1}{16}$ in. from each wire and then nailed to the slats sufficiently to prevent slipping. One man should be at each wire. The T squares are most serviceable if made with a movable head clamped by a thumbscrew, and of planed pine, about $2\frac{1}{2}$ in. $\times \frac{1}{2}$ in. Except in cramped quarters, the T squares will be set at right angles, and should be placed together in clamping, to insure that each set is at precisely the same angle.

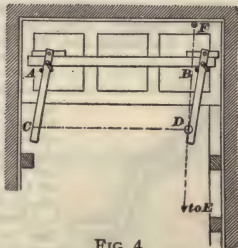


FIG. 4

Fig. 4 shows a cramped position, similar to what sometimes arises, in which the movable head gives more latitude in working. After clamping, the T squares are slid along the straightedge until close to the wire, but not touching it, and are there clamped by a G clamp, both men working at one T square. The ends of the T squares *C* and *D* must be supported on blocks so that the T squares lie approximately in the same horizontal plane. Everything up to the next step need be only approximately and quickly placed, but the greatest care must be exercised in measuring out equal distances *AC* and *BD* from the wires. If the wire vibrates, the middle of its swing must be determined by a pencil or pin. When holding a foot-mark (not the end of the tape) opposite the wire on the T square, an even number of feet should be measured, the point marked with a sharp pencil, and a pin inserted. When this has been done for both wires the parallelogram *ABDC* is obtained, in which the only essential is that *CD* shall be exactly parallel to *AB*, the line of the wires. The transit should now be set over the most convenient of the two points, as *D*. To get the azimuth of *DC* and, consequently, the line of the wires, sight must

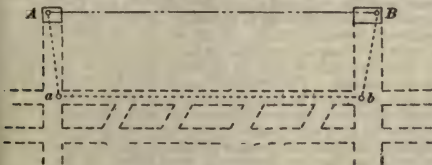

FIG. 5

be taken on a known point *E* for a backsight, and the angle *EDC* measured. Another point *F* must be established on the line of the backsight, in order that its course may be preserved after the instrument and T square are removed.

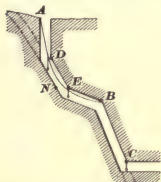
By this means the closing angle at *E* may be read after the wires are removed from the shaft. Underground, the method is the same, except that *DC* is the known course, and is used as the backsight. To give the coordinates of the instrument at *D* with the greatest precision, the angle *ADC* and the distance *AD* should be measured.

**Check Methods.**—The results obtained by the use of the methods just described should be checked as soon as an underground connection between

the hoisting shaft and air-shaft has been driven. Single wires are hung, one in each shaft, and the distance between them on the surface is measured. The latitude and departure of both *A* and *B*, Fig. 5, are known as they are tied in to the outside survey. In the mine, the stations *a* and *b* are occupied by the transit and the angles *A ab* and *abB* repeatedly measured. The underground distances *Aa*, *ab*, and *bB* are carefully measured. With these data, it is easily possible to calculate the latitude and departure of the mine stations *a* and *b*, and consequently the azimuth of the line *ab*, which serves as a base for all future extensions of the mine survey. It should be noted that Fig. 5 shows the simplest arrangement of the sights that is possible, but two; ordinarily there will be anywhere from four to ten or more stations required to carry the line from one shaft to another. As the surface and mine temperatures may be very different, particularly during the winter and summer months, a correction should be made for the expansion or contraction of the tape.

## SURVEYING SLOPES OR INCLINED SHAFTS

Where a single sight reaches from top to bottom of the slope, the problem is simple enough. A station can be established on the inside of the foot-wall plate at the collar and others in similar positions at each level. The instrument set up over any station can command the whole slope and the level opposite.



Where the slope is sunk on several dips, the survey is a much more difficult matter. Fig. 1 illustrates cases of common occurrence. The slope may be divided into sections like *ADEB*, which are convex downwards, and others such as *EBC*, which are concave downwards. As a rule a set-up can be avoided at the convex knuckles if desired, and need only be made at those that are concave.

**Bent Plumb-Line Method.**—Point *A* may be invisible from point *B*, but the survey may be carried from one point to the other by the *bent plumb-line method.*

Fig. 1

In this case, establish a station at *A*, the foot-wall side of the collar, the center point being a small nail head projecting horizontally. Attach a long plumb-line to this and carry the other end to *B*. Here it will probably be necessary to use a small screw-eye, with its head turned into the vertical plane of the slope for the center point. Pass the plumb-line through this and draw it fairly tight. Now attach a plumb-bob at an intermediate point and regulate the tautness so that the line is clear at all points. The curves in the slope may be such that two plumb-bobs may have to be hung, as at *D* and *E*, and even a third may become necessary.

As the plumb-line, perhaps 100 ft. long, is apt to be disturbed by the air-currents, it is often better to mark a point on a convenient timber near *D*, and another near *E*, so close to the string that there is no doubt of the points lying in exactly the same vertical plane as the plumb-line. If these points are once established, the string and weights can be taken out of the slope, leaving four points in the same vertical plane, and whose horizontal projections lie in the same course.

Now set up the transit at *A* and measure the azimuth angle from the backsight to *D*, thereby giving the bearing from *A* to *B*. If *D* should be invisible from *B*, depress the telescope after sighting on *D* and locate the point *N* in the same vertical plane, and so situated that it is visible from both *A* and *B*. Measure the vertical angle and distance to *N*. Now set up the transit at *B*, use the course *BE* for a backsight, and foresight to *C*. Measure the vertical angle and distance *BN*. The line *BN* might have been used as a backsight, and *E* serve as an additional check. The point *N* is really an intermediate station, but as it lies in the course *AB*, a set-up here is unnecessary. In simple cases, the bent plumb-line method is a very convenient one for carrying a survey from the surface to the first level, and a longer horizontal projection of the sight *AD* can be secured than if a set-up were made in the shaft at *D*; but in complicated cases, such as the one shown, it may often be quicker to make the extra set-up than to use the plumb-line. In all sights for determining azimuth, the vertical angles must be kept as low as possible, and the horizontal projection of the course long.

**Method by a Single Wire in the Slope.**—When surveying a slope by using a single wire, stretch a rather fine wire, free from kinks, down the slope, as shown in Fig. 2, being careful that it touches nowhere in the slope. Take two plumb-bobs provided with fine round strings and suspend one from *A* and the other

from *B* so that they nearly touch the same side of the wire *MN*. In order to have the plumb-lines as far apart as possible, the line at *B* must be quite long and a can of water provided to keep the bob from swinging. The plumb-line is fastened to a nail *B* nearly in the proper position. A bar of wood, with a block fastened to it, should be placed to one side and a little below *B*. The block must have a hole through which a small screw bolt can easily screw. On this bolt is placed a spool in which a groove is turned and which is sandpapered and greased so that the string will slip easily as the bolt is turned. Now, place the transit in line with the two plumb-bobs, as in an ordinary case of shaft plumbing. Repeat this operation below. The plumb-bobs in both cases hang in the same vertical plane and thus the true bearings are found underground. Even the plumb-lines may be dispensed with, but the method will not then be so accurate. The instrument will be set nearly in the vertical plane passing through the wire, leveled and sighted at *M*. The telescope should be dipped until the lowest point on the wire is visible and the amount by which the cross-hair and wire fail to coincide noted and the instrument shifted accordingly.

FIG. 2

But if this method is tried, the two points sighted at will not be nearly so far apart horizontally as the plumb-lines, and any error in leveling will also vitiate the result. This method of the single wire, however, provides no way of obtaining the coordinates.

---

# UNDERGROUND, OR MINE, SURVEYING

## INTRODUCTION

The same instruments and the same methods of measuring and recording angles and distances are used on the surface and in the mine. The chief difference between surface and underground work is one of detail only. In the mine, lamps are needed to give light, sights are taken to a string or to the point of a plumb-bob, and stations are placed in the roof and not in the ground. The main-line notes are kept in the same way above and below ground, but the method of taking and recording side notes is materially different.

Mine surveying in flat coal seams differs in minor details from that used in pitching seams, and this difference in detail has been greatly exaggerated until it has become a prevailing belief that anthracite (pitching) and bituminous (flat, usually) mine surveying methods are absolutely distinct. There is, in all underground work, a difference in the organization of the corps and consequently in some minor details in carrying on the work, depending on whether the survey of an entire and extensive mine is to be undertaken or whether, as is commonly the case, the survey is made merely to connect recent developments with those previously surveyed.

## FLAT WORK

Because it is necessary for the gangways, or entries, in pitching work to follow the foldings and twistings of the seam, the physical difficulties in the way of the surveyor are greater in that kind of work than in flat seams. In pitching seams, short sights and many of them are the rule; in flat work, long sights and few are general. In fact, in flat seams the headings or entries are commonly *driven on points;* that is, they are driven upon some predetermined course for long distances, even 2 or 3 mi. in the case of large properties. At regular intervals, pairs of cross-, or butt, entries are driven at right angles to the main entries; from these, in turn, the rooms are driven. Hence, the surveyor in the average bituminous mine (bituminous mines are commonly flat) is chiefly concerned with prolonging straight lines for several thousand feet in the case of butt entries, and up to 2, 3, or 4 mi. and more in the case of long main entries. The angles measured are chiefly right angles at the points where a butt entry intersects the main entry, or at the mouths of rooms driven from a butt entry.

The bituminous-mine surveyor is very rarely called on to make a complete survey of underground workings. He usually *moves up the points* (sights) at more or less regular intervals of time or of distance driven, measures the distance from the old set of points to the new, takes the necessary side notes, and at once plots them; the mine map, so far as the main headings and cross-entries are concerned, is thus up to date within a month or so at the most.

In fact, whether the sights are moved up with regularity or not, the mine foreman is always able to determine the position of the working face by measuring back from it to the last survey station appearing on the tracing or blueprint furnished him, and adding this distance thereto, laying it off in the direction the heading is being driven.

**Stations.**—An essential part of the equipment of the mine surveyor is a carpenter's brace and from three to six bits, or drills, which can be made from files thrown away by the miner. With these, a hole from ¾ to 1 in. in diameter and from 1 to 1½ in. deep may be drilled in the roof where a station is necessary. From ten to fifty plugs should also be carried by the corps. These plugs are pieces of poplar or other softwood about ⅝ to ¾ in. longer than the drill hole. They are square in section, the side being a little longer than the diameter of the hole in which they are to be used; the lower end may be roughly rounded. After the hole is drilled, one of these plugs is fitted in and driven home by blows from the hatchet until from ½ to ¾ in. projects below the roof. A *spad*, *spud*, or as sometimes called a *nail*, is then driven into the plug. The spads or nails are made from mule-shoe nails, through the flattened heads of which ⅛-in. holes have been drilled or punched. These spads may also be purchased from dealers in surveyors' supplies, but are commonly made by the blacksmith's helper at odd times.

Sometimes stations are made by driving a tack or nail in a tie, which has been notched or flattened with a hatchet to receive it, or by driving a spad in the collar or cap-piece of a set of timbers. Neither of these methods is to be recommended, as the position of a tie, and with it that of the station tack, is practically sure to be changed in a few months from the pounding it receives from passing cars, mules, and men, or from alining the track. Stations in collars are less liable to be shifted than those in the track, but as the pressure due to mining operations comes upon the timbers they, too, are apt to be shifted out of line. Sometimes stations that must be set at an exact distance from a previous station (as when a butt entry is to be started, say, 225.25 ft. from the main entry station) are of necessity made in a tie if the roof at the exact spot is not in condition to hold a plug (or has been shot down for an overcast). In such a case the station is placed in the tie and as soon as the butt entry or other place has advanced sufficiently to have sight plugs set in, these are placed, and the use of the tack abandoned.

In longwall work, much difficulty is experienced at times through the stations being shifted out of line through the settling of the overlying rocks. This settling may extend over a period of years or may stop after a few months. While the settling is in progress, the timbers must frequently be renewed, so that they and the constantly disturbed roof and floor afford a poor place for permanent stations. Hence, during the period of settlement at least, stations in longwall mines must be placed in the floor. For the foregoing reasons, combined with heavings of the floor as the weight comes unevenly upon the pillars, these stations are almost certain to be disturbed, and should not be used to extend a previous survey until one or more older stations have been reoccupied by the transit and the angles and distances remeasured to be absolutely certain that no such disturbance has taken place. If displacement has occurred, it will be necessary to go back along the line until three stations have been found in their original position. From these a new set of lines must be run, using the old stations if solid enough, remeasuring the angles and distances, but not necessarily retaking the side notes.

Stations are commonly marked by enclosing them in a circle, square, or triangle, or by a + mark of white paint. White lead, or Dutch white, thinned with linseed oil is ordinarily used, and is applied with an ordinary sash tool. If the paint has to be kept a number of days, it should be covered with water, which should be poured off before the paint is used.

In addition to marking the station itself so that it may readily be found, some system of lettering or numbering must be devised so that the stations may be distinguished one from the other. Stations on the main entry frequently have the letter M prefixed and are numbered in regular order from the drift mouth, thus, M–1, M–2, etc. Or the stations on the main entry may use the letter A, those on its air-course the letter B, those on the manway the letter C, and similarly for other parallel entries. As butt entries are usually known by a number corresponding to the order in which they were turned off from the main entry, the stations on such entries, while numbered consecutively, have prefixed to them the letter R or L to indicate whether the entry is turned to the right or the left of the main entry, as well as the serial number proper to the entry. Thus, L1–12 or 1L–12 indicates the twelfth station

on the first left-hand cross-entry, or, as commonly said, *on the first left.* Similarly R5–6, R–56, or 5R–6, is the sixth station on the fifth cross-entry to the right. If entries are driven from one side only of the main entry, the prefixed letters R and L may be omitted. In this case, the foregoing stations will be numbered 1–12 and 5–6, respectively. Air-courses are not usually run on sights. If they are, the stations in them may be numbered in the same way as those on the heading proper with a letter, such as A, to denote the fact that they are on the air-course. Stations coming between regular stations on an entry commonly receive the number of the preceding station with some letter added. Thus 56 D is a station on the fifth cross-entry at a point between regular stations 6 and 7.

Some corps number the stations in a heading as are stakes in a railroad survey. The station at the mouth of the heading on the main entry is called 0, and the first station in the heading will be, say, 2+56.29, the second 4+81.96, etc. This means that these stations are 256.29 and 481.96 ft., respectively, from the mouth of the entry. The distance between the stations is, of course, 481.96−256.29 = 225.67 ft. While this system of numbering shows at a glance the exact distance an entry has been driven, such large numbers may be a source of trouble and of possible error when used to describe the backsight, instrument, and foresight stations as entered in the field notes.

Rarely are stations numbered in the order in which they chance to be placed. It may happen that station 56 will be on the main entry, 57 on the fifth right, and 58 on the tenth left and follow, say, stations numbered 36, 48, and 51. This system, or want of system, is not commended, as it leads to confusion.

While the numbers of stations are frequently painted on the roof alongside the station mark, it is better practice to paint them on the rib a short distance before the station is reached. In this way the foresight man can see them without having to walk in a stooping posture.

**Sighting.**—Sights in underground work are commonly taken either to the point of a plumb-bob suspended by a cord passed through the hole in the head of the spad marking the station, or to the cord itself. In the first case, a lamp is held a short distance back of the point of the bob to render it visible against a background of flame. In the latter case, the cord is best illuminated by placing a white paper or cardboard behind it and holding the lamp in front and to one side. The string shows as a dark line against a white ground, but care must be taken not to confuse the string with the shadow it casts upon the paper.

What are known as *plumb-lamps,* or *plummet lamps,* are a great convenience. These are very heavy plumb-bobs, suspended in gimbals to ensure verticality, which are hollowed to form an oil chamber, and are provided with a wick. The bisection of the lamp flame, if the wick is turned low, affords a sufficiently accurate setting of the transit when placing room sights, surveying rooms, and even in moving up sights in a butt entry, provided the backsight is not too close to the instrument and the flame is not greatly disturbed by the ventilating current. It is obvious that the use of the plummet lamp, which will burn for several hours and is always ready for backsighting on, saves the labor of one man. In accurate sighting, the point or the cord of the plumb-lamp may be used as just explained. Where the velocity of the air is great enough to cause the plumb-bob to oscillate, long narrow bobs must be used, and these must be shielded from the direct current by the backsight man. In drafty places, a hole may be dug out in the ballast between the ties and the bob let into this shelter, the sight being taken to the string. Cords for suspending plumb-bobs should be braided to avoid twisting under the weight of the bob, should be well-oiled, and should be hung with a slip knot so that the point may be raised or lowered.

Various means are employed to illuminate the cross-hairs in the telescope. Commonly this is done by holding a lamp a little beyond, above, and to one side of the object glass. Sometimes a reflector is provided. This consists of a piece of silvered metal, inclined at an angle of about 30°, that is soldered on one edge to a metal ring that fits around the object end of the telescope. The reflector has an oval hole through it to permit the passage of the line of sight. The reflection of the light carried in the surveyor's cap sufficiently illuminates the hairs to permit their being centered upon an object. In some rare cases, transits have the horizontal axis pierced (the opening being closed by a piece of glass), through which hole a lamp held at the end of the telescope axis will throw enough light to render the cross-hairs visible.

**Centers.**—If stations are made in the ties, the transit may be set up over them exactly as in outside work. However, stations are commonly made in the roof. The transit may be set under a station if a center mark is punched in the collar surrounding the telescope and to which the transverse axis is attached. When the telescope is level, this mark is immediately above the point of a plumb-bob suspended from beneath the instrument. By slightly loosening the leveling screws, the plate may be shifted until the center of the instrument is exactly below the point of a bob suspended from the station spad. However, care must be taken in tightening the leveling screws, that the instrument is not thrown out of line. Commonly, the station in the roof is transferred to what is called a *center* placed on the floor, and over this center the instrument is set in the ordinary way.

The center may be made from a large square or hexagonal nut some 2 in. across. A wire nail or spad is set in the center of the hole in the nut, which is filled with melted lead or Babbitt metal. The point of the nail is cut off about $\frac{1}{2}$ in. above the top of the nut and sharpened with a file. Or a very satisfactory center may be made by boring a hole $1\frac{1}{4}$ in. in diameter and 1 in. deep in a thick plank, setting a brad in the center with its head down, and filling in with melted lead, at the same time holding the brad in a vertical position with its end projecting slightly above the top of the plank. After cooling, the brad may be sharpened as before.

A plumb-bob is hung from the station and the string adjusted until the point of the bob just clears the point of the center. By sighting across the two points at an angle of 90°, the point in the center may be shifted into coincidence with the point of the bob. If the center has been lost or forgotten, a plank may be laid across the rails under the station and the position of the point of the plumb-bob marked upon it with a pencil. After removing the plumb-bob and its cord, the transit may be set over the center or pencil mark in the usual way.

**Placing Stations on Line.**—Two cases of placing stations on line may arise: (1) The station may be on the prolongation of the heading line and at any indefinite distance from the instrument. (2) The station may (or may not) be on the line of the heading, but is at a fixed, definite distance from the instrument.

The first is the common case when the last station on a straight heading is, say, 200 to 250 ft. back from the face, and a new station must be set ahead and on line so that sight plugs may be placed from it. The transit should be set up at the station nearest the face, a backsight taken on an outer station on the line, and the telescope plunged. Where the roof is solid and from 25 to 50 ft. back from the face, the foresight man should hold his lamp against the roof so that its flame may be lined in by the surveyor, a smear with the lampwick or an X with a piece of chalk should then be made on the roof when the line is secured. The point of the drill may be placed on this mark and the lamp held behind it. If not in line, the drill may be shifted to the right or left until it is. The hole should then be started by pressing upwards and turning the brace. As the point of the drill is apt to slip on smooth rock, as soon as the hole has a grip, another sight should be taken to make sure that the drill is still in line. If it is not in line, a new sight should be taken and a new hole started a few inches away. The hole should be drilled to the required depth and the plug driven firmly home. The point of a spad should then be stuck in the plug near its center with the head hanging vertically and the eye facing the transit. Holding the flame of the lamp behind the spad, it must be moved to the right or left until its point is exactly in line. Still holding the lamp behind it, the spad should be driven firmly home, the blows of the hatchet being inclined so that the head of the spad may be driven to the right or the left as the transitman, who is following the work, may direct. When the spad is driven home, the lamp should be held behind its eye and, with gentle taps of the hatchet, it should be knocked to the right or left until the vertical hair exactly bisects the hole. For many purposes, the alinement is now sufficiently accurate. For important work, however, the plumb-bob should be hung from the spad and the final and exact alinement made by sighting to its point or to the cord. The distance between the old and new stations should be measured and if, in addition, the side notes are taken the work may be placed upon the mine map at once.

The second case arises when a branch or cross-entry is driven from the main entry, either to meet a similar place being driven toward it or to intersect another place at a fixed point. The instrument is set up on the main entry at the point nearest to that from which the branch road is to be driven,

a backsight is taken upon an outer station, and the telescope plunged. The foresight must now be placed not only on the entry line, but at an exact distance, say, 186.27 ft., from the transit. The tape must be stretched in line, and at the exact distance from the station, a pencil mark 3 or 4 in. long made at right angles to the line of sight. This mark may be made on the face of a tie that has been cleaned off, if one is at the right distance; or on a piece of plank made to span the space between two ties. The point of a tack or a brad should be placed in this line and a lamp held behind it. The tack must then be shifted until it is in line and driven home. If the distance the branch road is to be driven is short and the station at its mouth will not be needed again, the instrument may be set over the tack, and after setting the vernier at 0 or at the back azimuth or bearing of the entry line, the deflection angle, azimuth, or bearing on which the new place is to be driven may be set off on the upper plate and upon this line the sight plugs may be placed. The surveyor is recommended to always use the system of reading and recording angles with which he is most familiar, except, of course, when the system is inaccurate.

If the station must be preserved (which is commonly the case), the position of the tack just placed in the tie must be transferred to a permanent station in the roof. To do this, leave the transit as it was after setting the tack. Suspend a plumb-line from the roof, holding the string in such a way between the thumb and forefinger that when the helper says the point is directly over the tack, a smear of chalk (previously applied to the thumb) may easily be made on the roof. Hold the drill on the mark and have it lined in from the transit. After the bit grips the rock, again line in from the transit and check the distance measurement by again dropping a plumb-line upon the tack. Drill the hole and drive home a plug, which may be of somewhat larger surface area than the ordinary station plug. Draw a pencil line across the face of the plug by joining the holes left by the points of two brads set near the inner and outer edges thereof and which have been lined in from the transit. (These brads need not be driven up, as they are used only for giving the ends of the line.) Next suspend the plumb-bob over the edge of a knife blade (the thumb is too blunt), so that the cord is on the pencil line, and when the helper, by sighting across the point and the tack, announces that they are directly over one another (that is, the distance is exact) make a mark, with a pencil, on the plug. A spad may now be placed in this mark and should be on the entry line and at the proper distance from the instrument. However, before driving it home, check the alinement. After driving home, perfect the alinement by sighting to the point of the bob or to its cord. Some prefer, after the plug is driven up, to suspend the plumb-bob from a spad, which is shifted by the transitman to the right or left until in the line of the heading, and by the foresight man's helper inbye and outbye along the heading line until at the exact distance, after which it is slowly driven up, being checked during the process. By the first method, there is no trouble in placing spads within less than $\frac{1}{100}$ ft. of the exact spot and any desired degree of accuracy may be obtained by taking time.

**Placing Sights.**—The entries always and the rooms usually, in flat seams, are *driven on sights*. These sights are a pair of plugs set on the pre-determined line about 2 ft. apart in which are driven spads that are set exactly on line. Pieces of coal, iron nuts, or other weights are hung from the spads and before an undercut is made the foreman, miner, or machine runner sights across the strings and marks the center line on the face with a piece of chalk. Under ordinary conditions, sights should be moved up about every 200 ft. of advance in the working face; although this distance may be increased where the ventilation is good and lessened where it is poor. While a pair of sights may be placed near the face from an instrument station 200 ft. or more back therefrom, the better practice is to place a station ahead as just explained. The transit is then moved to this station, a backsight taken as before, the telescope plunged and the two sight plugs placed some 10 to 15 ft. ahead of the instrument, the final alinement being effected by bisecting the two eyes. This makes the survey station independent of the sight plugs and the spad in it is not apt to be pulled out of line, as will be the case if the station is one of the sight plugs. The practical certainty of finding the station in good condition more than repays for the labor of setting the extra plug and making the extra set-up.

While entry sights are commonly and naturally placed in the center of the opening, many consider it better to place them to one side and over, say, the right-hand rail. By so doing, a conscientious track foreman can use them to

keep his own work in line and, being proud of a fine piece of work, will urge the miners to drive the headings straight. With heavy trains and motors and the high speed required for large outputs, the importance of a straight track is apparent.

When rooms are driven on sights, usually each room is given a pair of sight plugs, but in some cases only every other room is so provided, the intermediate room being kept in line, as well as possible, by leaving a pillar of constant thickness on each side, which thickness is determined by measuring through the cross-cuts. As the direction of rooms is rarely of prime importance, sights in them are not moved up, unless it is absolutely impossible to see the face from them by reason of smoke, roof falls, etc. Room sights are commonly placed in the necks anywhere from 8 to 20 ft. from the entry line. Surveyors prefer to wait until the necks have been turned for a number of rooms before placing the sights in any of them. The instrument is then set up at any convenient station and the line of sight made to coincide with that of the entry. A series of tacks is placed in line the proper distance apart (when rooms are turned at 90°, distance = width of room + width of pillar) and are driven down into the tie or into a plank laid across the rails, one tack for each room. The instrument is set up over each tack in succession and a right angle to the heading line is turned and two sight plugs are placed in the room neck as far from the entry as possible. The distance of each tack from the entry station is noted and the distance from the line of the entry to the outbye room sight plug is also measured and recorded. Room sights may be set by bisecting the eye of the spad and are commonly placed 18 in. to 2 ft. from the rib. Where rooms are inclined to the entry, the distance between their centers measured along the line of the entry is found from the formula:

$$\text{Distance} = \frac{\text{width of room} + \text{thickness of pillar}}{\sin \text{angle of inclination}}$$

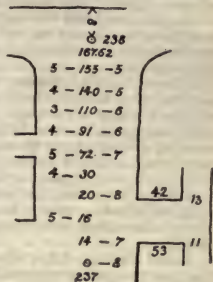
**Surveying and Note Keeping.**—The laws of most states require that the mine workings be surveyed and mapped at least once every 6 mo. If the necessary measurements and side notes have been taken at the times the entry sights have been moved up and have been mapped, the mine, so far as the main roads are concerned, is always within a few weeks of being up to date. If this has not been done, the procedure will depend on whether lines of sight are carried up one or both entries of a pair. If each entry has its sights, the 0 end of the tape should be held at the last station appearing on the map and the tape stretched out to the next station. The surveyor may then walk along the tape and, when opposite a break-through, note the distance to both sides of the opening as say +256 to +267 (the opening being 11 ft. wide). The assistant should carry the 0 end of a tape (usually a 50-ft. metallic tape) to the rib at each side of the cross-cut, and the surveyor should measure the distance to the nearest ½-ft. mark to these points from the entry line and note whether the break-through has been driven to the right or left from the entry. Room necks may be located in the same way.

It is advisable, where the entry is crooked, to note the places where the entry comes nearest and farthest from the rib. Many surveyors do not take offsets to the corners of the pillars made by the various openings, merely noting these *plusses*, or distance measured along the tape opposite which these openings come. When so mapped, the entries appear perfectly straight, which makes an attractive but inaccurate map. When the exact distance between stations as well as the necessary vertical angles have been taken at the time the stations were moved up, the use of a transit is unnecessary when making the entry surveys, but it is highly advisable to remeasure these distances as a valuable, in fact as the only possible, check on the original distance measurements until a close is made and the survey calculated.

After taking the notes between the first pair of stations, those between the next pair should be taken, and similarly until the foresight man with the tape reel is at the last station. This may be anywhere from 25 to 200 ft. from the face. To get the entry line, the foresight man, carrying the reel, should be sent ahead; and when he is at the face, the tape may be brought in line by sighting over the entry sight plugs to a lamp held on the reel. After completing the side notes on one entry, those on the parallel entry or entries are taken. These notes are entered in tabular form as taken, beginning at the bottom of the page and working toward the top. The *plusses*, or distances from the instrument, are in one column and in other columns are the offsets to the corners of the openings, each placed in the horizontal line of the proper *plus*.

Each surveyor will have his own set of abbreviations: Common ones are Bt for break-through (or cc for cross-cut), Rm for room, r or rb for rib. Thus +256, 5.5 Btr, means that at 256 ft. from the station and 5.5 from the line is the corner of a break-through, which is driven to the right. Sometimes

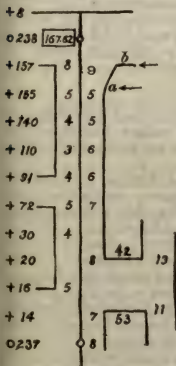
Fig. 1

these notes are amplified and illustrated by sketches as shown in Figs. 1 and 2. In most mines, particularly in the case of butt entries, only the room entry is driven on points, the air-course being kept as nearly as possible to a parallel line by maintaining a constant thickness of pillar between it and the room entry. In this case, the distance from the tape or the offset is measured not only to the edge of the cross-cut, but also to the corresponding edge of it on the air-course and to the far side of the air-course as well. These three measurements might be recorded as follows: +254, 5—26—37 and +263, 6—26—36. The plusses are at 254 and 263 ft. from the station and show that the break through is 9 ft. wide. At the first plus, the distance to the corner of the break-through is 5 ft., the distance to the corresponding corner on the air-course is 26 ft. (the pillar being 26−5=21 ft. thick), and 37 ft. to the rib of the air-course, which is 37 −26=11 ft. wide. At the inner side of the cross-cut the pillar is 26−6=20 ft. thick, and the air-course 36−26=10 ft. wide. The advantage in measuring continuously out from the tape is twofold: The surveyor does not have to leave the entry, and consequently has time to enter his notes in a concise and cleanly way as the foresight man does the running around and, above all, by standing on the entry he is able to keep the small tape with which the side notes are taken, exactly at right angles to the large tape; further, notes thus kept are easier to map, requiring but one setting of the scale, regardless of the number of offsets taken from any plus.


It is usual to make sketches as the side notes are taken, in order to illustrate and make plain any points that might be obscure to the office man that plots the notes. Two forms of such notes are shown in Figs. 1 and 2; both are of the same entry, the air-course parallel to which is located by measurements through the break-throughs. Such notes are begun at the bottom of a page and sketched upwards in the order in which they are taken. The form shown in Fig. 2 is preferable as being the clearer. It will be noticed that in both forms

Fig. 2

the air-course is located not by continuous offsets, but by single measurements through the pillar, the disadvantages of which method have been explained. The ends of pillars are so rarely square that it is commonly difficult to decide at just what point a break-through begins. This is illustrated at *a* and *b*, Fig. 2. The proper way to locate such a rounded pillar is to take a plus and offset at the point where the pillar begins to round (+155, *a*) and a second plus and offset where a sight tangent to the end of the pillar may be had (+157, *b*). The distance between the stations is always noted on the sketch. In the case illustrated, the distance from the last station to the face is shown (8 ft.) beyond the figures for the length of the line.

The survey of a series of rooms in which sights have been placed is a comparatively simple matter. The sight strings are lowered (the miner generally keeps them hung up against the rib), and the helper goes to the face, unwinding the 400-ft. tape as he goes. The 0 end of the tape is held at the first or outer sight plug, the distance of which from the line of the entry was measured when the sights were placed. The transitman, by means of the room sights, places the man at the face in line and takes the side notes in the manner explained. If the rooms have not been driven on sights, it is customary to place a tack in a tie at the mouth of each room, the tacks all being on the entry line, but at irregular distances apart as they are placed so that the instrumentman may see the face. After the tacks are lined in, their respective distances from the instrument are measured and recorded.


The instrument is set over the tack at the first room, the vernier is set at the azimuth or bearing of the entry, and a backsight is taken upon some station. The foresight man unwinds the tape on his way to the face, where he holds the reel on an **X** he has marked on the coal in chalk, and to which the transitman takes a sight. The 0 of the tape being at the instrument, a line is established to the face, and the side notes may be taken as before explained. In many instances a line is run up every other room only (thus, up rooms 1, 3, 5, 7, etc.) the intermediate rooms being located with sufficient accuracy by offsets through the cross-cuts.

It sometimes happens that practically all the rooms on an entry are so blocked with falls of slate that it is impossible to see to the face and thus survey each room separately. In such a case, a line is run from the entry up some room not blocked by falls and a survey made of the faces of the rooms by running a line along them through the break-throughs. If desired, stations may be established in ties in each room near the face, and sights taken down the room until stopped by the falls; or a line may be run down every other room. Usually, offsets from the line along the face will locate the pillars and face line with sufficient accuracy for all practical purposes, particularly if a good portion of the rooms have been mapped from surveys made before the fall of roof took place.

**Level Notes.**—All level notes are kept as in outside work, with the exception that, as the rod is reversed in getting the elevation of a station in the roof, the record of the reading is prefixed with a minus sign. A record of such a reversed rod, when the target is 3.78 ft. below the station, is recorded $-3.78$.

A shaft is measured (if deep) by a fine steel wire running about an accurately graduated wheel (a sufficient number of turns being laid to prevent slipping) and noting the number of turns before the bottom is reached. The wire may be measured before and after the operation, to insure against stretching. An aneroid mining barometer, if in good condition, will give quite accurate results if a number of trips are made between top and bottom, to give an average. In this case the barometer must be left quiet 10 or 15 min., to be sure that it has expanded or contracted to the proper degree. For rough measurements, the length of the winding rope between top and bottom is taken.

By one of these methods a bench mark should be located below, connected with the outside work, and referred to tide water. The rod must be reversed to get the elevation of all stations in the roof, and all such readings are noted with the minus sign, as $-4.32'$ (read 4.32 ft. below station). Roof stations are almost certain to settle, from the pressure of the superincumbent rocks. To check such settling, the distance from roof to floor must be accurately measured. Some measure from floor to rail of track; this is inaccurate, as the track may be shifted or the grade changed in making repairs, or to take out a sag. Whenever a level survey is begun the distance between roof and floor should be measured to see if it agrees with the notes. If it differs, the fact should be stated under the original notes, as a check for future work.

## PITCHING WORK

The survey of workings in highly inclined coal seams does not differ in methods from those employed in surveying mines in flat seams, but there are sundry minor modifications in detail varying from mine to mine, as peculiar or local difficulties have to be overcome.

**Stations.**—The seams are usually folded along the line of strike so that the entries, or gangways, that are driven approximately upon a water-level, are curved and crooked to the same extent as the seam. For this reason, gangways cannot be driven upon sights, and stations are established as needed as the survey proceeds. As these stations are placed solely with a view to obtaining as long or as many sights from one point as possible and as the spads used do not have to be set exactly on line, much smaller drills and plugs may be used in pitching than in flat work. In some cases, the holes are only $\frac{1}{8}$ to $\frac{1}{2}$ in. in diameter and but $\frac{1}{2}$ in. to 1 in. long as maximum. Various devices for quickly establishing these more or less temporary stations have been adopted in the anthracite regions of Pennsylvania, some of which are here given.

1. The simplest top station is a shallow conical hole, made with the point of the foresight man's hatchet, which is dug into the top rock and rotated, and is called by some a *jigger* station. Corps using these entirely have a jigger consisting of a steel-pointed extension rod, with an offset holding a paint brush. The rod is long enough to allow the point to be driven into the roof at any height, and its rotation marks a circle with the brush, which is also used to mark the number beside it. Centers are set under such

stations and sights are given by another tool—also called a jigger. This is an extension rod, beyond the upper end of which projects a piece of sheet iron shaped like an isoceles triangle, with the upper and smaller angle cut off so as to form an end $\frac{1}{4}$ in. broad, and in this end is cut a **U**-shaped groove.

The sights are given and the centers set by putting the plummet cord in this groove, and placing the end in the jigger hole in the roof. The cord must be more than twice the length of the section of the place, as it must be held in the hand, run over the jigger notch, and hung vertically to the plummet, which must come to the floor when the stations are set. The rod and cord are held in the left hand, and the right is free to steady the bob, give sight, or set the center. The advantages are the quickness with which the centers are set and the sights given, and the ease with which the highest stations are reached. The disadvantages are the impossibility of making the jigger hole perfectly conical, so that the jigger can be set in the same place on two successive sights, and the plummet cord will hang exactly in the same place.

2. A twist drill $\frac{3}{8}$ in. in diameter is used to make a hole in the roof; a piece of cord—or, better, a copper wire—is placed across this, and a hardwood shoe peg is driven into the hole and binds the cord tight. The plummet is tied to the lower end. A cord will soon rot, and, if in the gangway, is pulled out by the drivers for whip lashes, while the wire is more permanent; but even this will be pulled out by catching in the topping of a car in a low place.

3. The use of spads is dispensed with, and all the stations put in rock roof where possible. A $\frac{1}{2}$-in. twist drill makes a vertical hole 1 in. deep. Into this, when a sight is to be taken, the foresight man puts a steel clip with serrated edges. This is made by bending upon itself a thin piece of steel $\frac{3}{16}$ in. wide. When the ends are pressed together it will go into the hole, and the spring of the sides and the serrated edges hold the clip in the hole so that it is hard to pull out. The cord passes through a hole in the center of the bend and is, therefore, in the center of the hole—no matter how the clip is inserted. It is removed by pressing together the ends of the clip. This is the easiest and quickest way of working, as there is no eyehole to be freed from dirt and no knot to be tied and untied. The hanging of the plummet takes a fraction of a second, and the station will remain as long as the roof keeps up. The disadvantages are the putting of the holes inclined to the vertical by a careless man, and the many roofs that are unfit for piercing with a twist drill.

Stations are generally marked upon some regular system, as in flat work, although in some mines the objectionable practice of numbering stations at random as they happen to be placed still prevails. In the case of leased properties two surveys will commonly be made, one by the operator and another by the land owner. When this happens, each corps will have its distinctive mark as, for example, the one a circle and the other a cross (+), with possibly a distinguishing letter selected from the name of the corps as a further means of identification. If both corps use the same station each will place about it its distinguishing sign and number, and the notes will state "Sta. 617 = Sta. 432 of (          ) Corps."

**Surveying Methods.**—The method of surveying gangways and keeping notes does not differ from that employed in flat seams, except from the fact that three consecutive stations not being in line, a deflection angle and bearing or azimuth must be read at each set up. As the grade between stations may be, in fact commonly is, pronounced, particular attention must be paid to reading the vertical angle. Parallel entries (room entry and its air-course) are commonly at such a distance above or below one another that it is not usually possible to locate the one by measurements made through the crosscuts from the other and a separate line must be run in each. In case it is possible to locate the air-course by means of offsets from the main gangway, a clinometer, frequently a brass protractor with a plummet attached, must be hung from the stretched tape to give its angle of inclination. All such inclined offset sights must be reduced to the horizontal before being mapped.

If the seam pitches more than 30°, the rooms are worked with batteries; the heavy timbers forming these usually preclude the possibility of sighting from the gangway to the face. Work of this kind is surveyed by lines out the gangway and back through the faces of the rooms, which are generally clear of timber. The line along the face should be tied into the gangway line as soon as opportunity offers.

If the seam makes much gas, sights must be taken to safety lamps unless the portable battery hat lamps are used. The latter afford a very satisfactory light and, being absolutely clean, are preferable not only to the ordinary safety lamp in gaseous mines, but to the oil lamp in any mine.

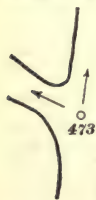
The angle of dip of the seam should be taken at each station and at intermediate points if it changes radically. The thickness and quality of the coal should be observed frequently and changes of importance noted on the map.

**Locating Pillars for Surface Support.**—It is customary to leave unmined pillars of coal to support important buildings, reservoirs, etc., on the surface. The usual method of locating these pillars is to extend vertical planes through the boundary lines of such objects, and leave untouched all parts of the superincumbent beds embraced by those planes. This is accurate only when the strata are horizontal or vertical, as beds settle normally to the planes of the strata and not in a vertical line in case the open spaces are stowed. If the spaces are left open, they are first filled by falls, and then the settling goes on according to the above rule. No cut is necessary to show the method of settling, and the place where the bed is to be left untouched may be found as follows: *Draw a vertical section through the point to be supported, and also the underlying bed on the line of the dip of the bed—the section being accurately drawn to any scale. Draw through the extremities of the object to be supported, lines to the bed, which will make right angles with it. The space included will give the dimension of the pillar measured along the dip of the bed, and the dimensions of the object taken at right angles to the first plane will give the other dimension of the pillar.*

## MINE CORPS

The number of men required in making a mine survey and the nature of their duties depend on the nature of the work to be performed. If sights are to be moved up two men, the transitman and foresight man, can do the work; but if distances are to be measured, a third man is advisable to assist with the tape if time is an object. The third man is essential if stations are to be set at exact distances from the instrument. In all ordinary survey work where offsets are to be taken, four men are essential and five are advisable. There must be two men to hold the long tape between stations on the entry, and two to hold the tape with which the offsets are taken, one of whom may be the transitman, but it is better to have a special crew for taking offsets, leaving the surveyor free to record the notes, determine the position of the stations, etc. Much time will be saved if one of the four men can set up the transit and read the angles.

When making a complete survey of an extensive property, particularly in pitching work where short sights are the rule and branch gangways on divers grades are common, it is a material help to place the survey stations before an attempt is made to measure the angles or distances. To do this,



the transitman will require two assistants and the services of a mine foreman or other official familiar with the workings and who will, in emergencies, hold a lamp where needed. The backsight man remains at the station from which the survey is to start and the party goes ahead to the most distant point therefrom that the lamp is visible. At this point, a station is established in the roof with the drill, plug, and spad, and its proper number painted on the rib or roof. The backsight man comes up to the new station and the party goes ahead locating a second and succeeding station or stations as may be needed. Very frequently several sights must be taken from one station, a common case being that shown in the accompanying figure, where the road forks. Here a helper is sent up each branch, the mine foreman holding his lamp at the backsight, and the transitman shifts his position until he finds a point from which the three lamps are visible and there establishes a station. For this work the transit is not necessary, only a bucket holding the brace, and drills, plugs, spads, and a hatchet, and possibly a 100-ft. tape, being taken into the mine.

## CARE OF INSTRUMENTS

The transit should be removed from the tripod and placed in the instrument box with its plates unclamped when not in use. When going to and from work, the transit should not be carried on the transit head, or the spindle will become sprung. Nor should it be carried with the arm crooked under the telescope, as the weight comes on the axis, and that soon gets sprung so that all the adjusting in the world will not make it work right. When carried in the hand, it should be reversed and the hand slipped under the compass plate and brought over so as to clamp both plates. In this way there will be no strain on any part. The person carrying the transit should be the first to

ascend a slope or any pitching place and the last to descend, so that loose stones or dirt that may be dislodged may not affect or endanger the instrument or trip the carrier. He must be sure that the tripod head is screwed firmly on the tripod. The possible slip of the instrument through not observing this caution may be a source of trouble in the failure to agree of the duplicate angles read at each station. As soon as the corps comes back from the mine, the tape must be stretched, tested, wiped, and oiled. It can be inspected to see if marks are too much worn, or it stands in need of mending, the marking pot is cleared of muck, and fresh white paint is mixed, if the corps is going out in 24 hr.; the plummets will have their strings overhauled and freed from knots; hatchets will be sharpened, and axes ground, pouches overhauled, and a supply of tacks or spads taken. The transit is set up and wiped with a cloth wet with alcohol, so as to remove dirt, oil, and paint. If water has gotten between the graduated limb and compass box, the verniers must be uncovered and the whole wiped dry. If sulphureted hydrogen from the powder smoke has tarnished the silver surfaces of any of the graduated circles, it must be removed with whiting. Alcohol should be always used instead of water, as it will quickly evaporate and leave the parts dry. The telescope glasses are then wiped with soft chamois leather, and the instrument is tested for want of adjustment before it is put away in its box.

How often the transit will require adjusting depends on the quality of the instrument and the care it receives when in use. When moving up sights by backsighting and plunging the telescope, the adjustment of the vertical hair must be perfect or the foresight will be to the right or to the left of the prolongation of the line joining the backsight and instrument stations; this adjustment is, thence, of prime importance to the surveyor in flat work, who is chiefly occupied in moving up sights as the workings advance. This adjustment is also of importance when reading deflection angles by the methods explained. Sights may be set without regarding the adjustment of the vertical hair, by setting the vernier at 0°, backsighting, and turning off an angle of 180°, but this involves two accurate readings and settings of the vernier. Deflection angles may be determined in the same way, by subtracting the included angle from 180°, and with the same objections to the method. A method sometimes employed to move up sights, which is independent of the cross-hair adjustment and does not require the reading of an angle is as follows: Assume that stations numbered, say, 200 and 201 are those nearest the face and that Sta. 202 is to be placed on the line 200–201 prolonged. Set up at Sta. 200, and foresight upon Sta. 201, remove the plumb-bob and cord from Sta. 201 and set Sta. 202 at the proper distance ahead on the line thus prolonged.

For plumbing wet shafts, kerosene resists the extinguishing power of water better than fish oil, and is less readily blown out by a strong ventilating current. It makes more smoke, and, in tight headings, or mines with poor ventilation, with a large party, fouls the air much more readily than fish oil. Sometimes a mixture of the two is burnt in very drafty places, where it is hard to maintain a light. Kerosene is burned in the plummet lamp unless it is used with the safety attachment. Sweet oil, or any oil burning without smoke, must then be used. Smoke clogs the openings in the gauze, restricts the entry and escape of gases, and, especially if the gauze is damp with oil, may ignite and communicate the flame from within to the outside body of gas.

---

# TRAVERSING AND MAPPING

## TRAVERSING

The *latitude* of a point is its distance north or south of some *parallel of latitude*, or line running east and west. The *departure* of a point is its distance east or west of some *meridian*, or line running north and south; it is the same as the *longitude* of the point. Latitudes are measured in a direction at right angles to the departures. The distance that one end of a line is due north or south of the other end is the difference of latitude of the two ends of the line, and is called the *northing* or *southing*, or simply the latitude of the end considered. The distance that one end of a line is due east or west of the other end is the difference in longitude of the two ends of the line, and is called the *easting* or *westing*, or simply the departure.

The process of calculating and tabulating the latitudes and departures of the courses of a survey is known as *traversing the survey*. To do this, all distances

must either be measured horizontally or be reduced to horizontal distances by means of the vertical angle. The horizontal angles must either be read as quadrant courses, or must be reduced from azimuth to quadrant courses.

$$\text{Latitude} = \text{distance} \times \cos \text{ of bearing}$$
$$\text{Departure} = \text{distance} \times \sin \text{ of bearing}$$

Below is given, in tabular form, the calculated notes of a closed compass survey. All the work shown should be kept in ink in the permanent office record books. The notes in the first three columns, headed Station, Bearing, Distance, are the same as the corresponding columns of the field notes. If the field notes show that the distances were measured along the

TRAVERSED SURVEY NOTES

| Station | Bearing | Distance | Latitude | | Departure | | Total Latitude | | Total Departure | |
|---|---|---|---|---|---|---|---|---|---|---|
| | | | North | South | East | West | North | South | East | West |
| 1–2 | N 35° E | 270.00 | 221 | | 155 | | 221 | | 155 | |
| 2–3 | N 83° 30′ E | 129.00 | 15 | | 128 | | 236 | | 283 | |
| 3–4 | S 57° E | 222.00 | | 121 | 186 | | 115 | | 469 | |
| 4–5 | S 34° 15′ W | 355.00 | | 293 | | 200 | | 178 | 269 | |
| 5–1 | N 56° 30′ W | 322.56 | 178 | | | 269 | 0 | 0 | 0 | 0 |
| | | | 414 | 414 | 469 | 469 | | | | |

slope, as would be the case in an ordinary transit survey, two extra columns should be provided, one for the measured distances and another for the vertical angles. If the elevations are to be deduced from the vertical angles, something that is necessary if a topographic map of the property is to be made, two additional columns will be needed, in one of which should be placed the differences in elevation of consecutive stations, and in the other, the total elevation of each station above sea level.

From the latitudes and departures of the individual stations, it is customary to determine the latitude and departure of each station with reference to the first station of the survey. These are commonly called the *total latitudes* and *total departures*, or *total northings, southings, eastings, or westings*, as may be.

The latitudes and departures of the individual stations are calculated by the formulas given. The total latitudes and departures are obtained by adding continuously and algebraically to the assumed latitude and departure of the first station, the latitudes and departures of the individual stations. The first station is frequently called the origin of coordinates, and its northing, southing, easting, and westing are commonly taken as zero (0). As a check on entering the latitudes and departures in the right columns, it should be noted that when the bearing is less than 45°, the departure is less than the latitude; and when the bearing is greater than 45°, the departure is greater than the latitude.

**Errors in Closure.**—If the survey is a continuous one around a tract, and ending at the place of beginning, the sum of the northings should equal the sum of the southings, and the sum of the eastings should equal the sum of the westings. Or, in other words, the sum of all the latitudes north, should equal the sum of all the latitudes south; and the sum of all the departures east, should equal the sum of all the departures west. It is evident that by coming back to the place of beginning the surveyor has traveled the same distance north as he has south, and the same distance east as he has west. However, in practice, as has been intimated under the heading Closing Surveys, no such agreement is possible. In fact, should a survey actually balance or close, it should be assumed that the closure is apparent and not real; the sum of the errors in one direction being exactly offset by the sum of the errors in the opposite direction.

The *error in closure* of a survey is the ratio that the length of the line joining the initial and final stations (as determined by the survey) bears to the

entire distance run. The length of this line is that of the hypotenuse of a right-angled triangle of which the errors in latitude and departure are the two sides. Thus, if the coordinates of the starting point are 0, and after running around a tract of land a distance, by survey of, say, 25,000 ft., it is found that the total eastings exceed the total westings by 4.25 ft., and that the total northings exceed the total southings by 1.5 ft., the survey will have failed to close by $\sqrt{4.25^2 + 1.50^2} = 4.51$ ft. The error in closure will be $25,000 \div 4.51 = 1$ ft. in 5,543 ft. (about). The bearing of the line of error (as it may be called) may be found from the formula:

$$\text{Tan bearing} = \frac{\text{error in departure}}{\text{error in latitude}} = \frac{4.25}{1.5} = 2.83333,$$

from which the bearing is N 70° 34′ E. That is to say, owing to errors in measurement, the final point instead of coinciding with the initial point, is found to be N 70° 34′ E, 4.51 ft. from it.

**Balancing Surveys.**—In surveys made with the compass and chain, it may be safely assumed that the failure to close is as much due to errors in angular measurement as in chaining. In this case, the latitudes and departures may each be corrected by certain amounts, some being increased and other being decreased, until a perfect balance is secured between the northings and southings on the one hand and between the eastings and the westings on the other by means of the following rule:

**Rule I.**—*The correction to be applied to any particular latitude or departure is to the total error in latitude or departure as the corresponding distance is to the entire distance covered by the survey.*

Each correction is to be applied in such a way as to diminish the whole error at the particular station.

In the case of surveys made with the transit, the angular measurements are highly accurate and it is very probable that errors in closing are due almost entirely to incorrect chaining. This is particularly so if the sum of the deflection angles is 360° (in which case the survey closes exactly in angle) or is not more than 1′ different for each mile or two (averaging, say, fourteen stations per mile) surveyed. In this case the rule for determining the corrections to be applied to each individual latitude or departure is:

**Rule II.**—*The correction to be applied to any particular latitude or departure is to the whole error in latitude or departure as the corresponding latitude or departure is to the arithmetical sum of all the latitudes or departures.*

As before, each correction should be so applied as to diminish the whole error at each station.

**Locating Special Work.**—The rules given for finding the error in closure of a survey, as well as its bearing, are applied to determine the length and bearing of a line (as that of a tunnel or entry) required to connect two points whose latitudes and departures are known. Thus, suppose that it is required to connect Sta. 57, whose latitude is 2,046.25 N and departure 18.76 E, with Sta. 49 whose latitude is 1,625.75 N and departure 159.26 E. It is apparent that Sta. 49 is $2,046.25 - 1,625.75 = 420.50$ ft. south, and $159.26 - 18.76 = 140.50$ ft. east of Sta. 57. The distance between the two stations is $\sqrt{420.50^2 + 140.50^2} = 443.35$ ft. Again,

$$\text{Tan bearing} = \frac{\text{difference in departures}}{\text{difference in latitudes}} = \frac{140.5}{420.5} = .33413$$

whence the angle is 18° 29′. As Sta. 49 is south and east of Sta. 57, the bearing and length of the line joining Sta. 57 and Sta. 49 is S 18° 29′ E, 443.35 ft. It must be noted that the exact tangent of 18° 29′ is .33427, or .00014 more than the calculated one. In the distance between the stations, 443.35 ft., a line run on a bearing of S 18° 29′ E will miss Sta. 49 by .06 ft. Hence, an exact closure cannot generally be obtained with an instrument graduated to minutes only. The distance between the stations may be found without having to extract the square root, the bearing having been obtained, by the formula

$$\text{Distance} = \frac{\text{difference in latitudes}}{\cos \text{ of bearing}} = \frac{420.5}{.94842} = 443.36 \text{ ft.}$$

# MAPPING

**Laying Off a Map.**—It is very commonly the case that a mining property has its greatest linear dimension in any other direction than an east-and-west line. Thus a property containing, say, 2,000 A., might have approximate dimensions of $2\frac{1}{2}$ mi. in a general northeast and southwest direction, and of

$1\frac{1}{2}$ mi. at right angles thereto. Mine maps are required by the laws of most states to be on a scale of 100 ft. to 1 in., although 200 ft. to 1 in. is permissible in some cases. On the larger scale, the property just described would have a northeast and southwest length of 128 in. (10 ft. 8 in.) and a length at right angles thereto of 79.2 in. (6 ft. 7.2 in.). It is apparent that if such a property is mapped with its meridian at right angles to the length of the paper (that is like ordinary maps in an atlas with the north toward the top), a goodly portion of the survey will extend both above and below the top and bottom edges of any paper now made for draftsmen's use. Such a property must be laid down with its longest dimension parallel to the longest dimension of the paper, regardless of the direction of the meridian.

To determine the best way to lay off the map on the paper, it is customary to make a skeleton map of the property on a small scale, say, on one of 1,000 ft. to 1 in. (in the foregoing case the dimensions would be 12.8 in.×7.92 in.) and lay this upon a sheet of paper that represents, on the same scale, the paper to be used for the finished map. By shifting one upon another, a position will eventually be found where the property may be drawn upon the sheet. By pricking through with a needle point, the stations may be transferred from the skeleton map to the sheet representing the drawing paper, and the connecting lines drawn. A border should be drawn around this minature map at one-tenth the distance from the edge that the border will be from the edge of the large map. There will now be available for laying off the paper, a minature reproduction of the outlines of the finished map. To draw the coordinate lines, lay off upon the large sheet, using their location on the small map as a guide, the most easterly and most westerly corners of the property. Any other two corners will do, provided they are separated by as long a distance as is conveniently possible. Connect the selected corners by a line and calculate the bearing thereof. If it is assumed that this line has a bearing of N 58° 30′ E, all lines making an angle of 58° 30′ to the left of this base will be north-and-south lines, or meridians.

When mapping extensive surveys, it is a slow and usually an inaccurate process to measure from the initial station the total latitude and departure by which every other station is located, as many of the distances will be very long, from 5,000 to 10,000 ft. or more (from 50 to 100 in. on the scale of the map); therefore, mine maps are laid off in a series of squares 1,000 ft. (10 in.) on edge with their sides in the meridian. To locate a station whose coordinates are, say, latitude 8,250 N and departure 6,500 E, measure along the meridian marked 6,000 a distance 250 ft. north of its intersection with the parallel marked 8,000. At this point erect a perpendicular to the meridian (or draw a line parallel to the latitude) and lay off along it a distance of 500 ft. to the east. The point thus plotted will have the coordinates in question.

To draw these squares, place a meridian, determined by the method explained, upon the map somewhere near the middle. Upon this, mark a series of points exactly 10 in. apart. Through the extreme points draw perpendiculars to the meridian by any of the methods of geometry. Upon these parallels lay off spaces of 10 in. both east and west from the meridian and through these points draw the remaining meridians. On the most eastern and western meridian thus established, lay off further spaces of 10 in., the points marking which may be connected with those on the first meridian laid down upon the map, thus completing the work. These squares should be laid off in pencil and lightly inked in with the utmost accuracy. The work should be done during a single day when conditions of temperature and humidity are as nearly constant as possible, as atmospheric changes will cause paper to expand or contract and thus change the size of the squares. In the case of large properties, the proper placing of the meridians and parallels so that all the corners, etc. will come on one sheet of paper is a matter of painstaking work. Often the shifting of the meridians or parallels 1 or 2 in. either way will accomplish this much to be desired result; and this can only be done by cut-and-try methods combined with more or less calculation and recalculation of the coordinates of the extreme points as the meridians and parallels are shifted. If the map will extend over upon a second sheet, this should be laid off in squares in a similar manner to the first, and should have laid down upon it enough of the workings, etc., appearing last upon the first sheet, that it may be used independently of it. In other words, the second sheet of the map should overlap for 2 or 3 in. on that of the first sheet.

The question of numbering the meridians and parallels or, what is in effect the same thing, determining the location of the zero of coordinates, is a matter of importance. In most maps, some one meridian will be marked 0,

those to the right of it will be designated as 1 E, 2 E, 3 E, etc., and those to the left, 1 W, 2 W, 3 W, etc. Similarly, some one parallel will be marked 0, and those above and below it will be respectively 1 N, 2 N, 3 N, etc., and 1 S, 2 S, 3 S, etc. A better plan is to call the most westerly meridian and most southerly parallel 0. In this way all the latitudes will be north and all the departures will be east, all additions made to determine the total latitudes and departures will be algebraic without shifting from one column to another and there will be but two columns for the total latitudes and departures instead of four. Under this plan, there is much less liability to error when making calculations involving differences in latitudes and departures, for these differences will always be obtained by subtraction and never by addition, as is frequently the case when the first system of numbering the meridians and parallels is used. For example, under the first system two points having latitudes of 200 N and 300 S, respectively, will differ in latitude by $200+300 = 500$ ft.; under the second system, these same points will have latitudes of, say, 800 N and 300 N, the difference being $800-300 = 500$, as before.

**Mapping the Field Notes.**—The stations made to determine the boundaries of the property are first placed upon the map, using the total latitude and departure of each for this purpose; the method having been described. After two consecutive stations have been plotted, as a check on the work, the distance between them should be measured. This should agree with the horizontal distance reduced from the field measurements. After the survey stations are plotted, the property corners should be mapped in the same way, checking up the plotted distance between them and the survey station from which they were determined. By joining these corners, the outer boundaries of the property will now appear upon the map. Preferably by means of a protractor reading to minutes and using any convenient meridian as a base, the side shots to buildings, runs, etc., as determined from each station, should be laid off. These directions should be transferred to the proper station and the distance measurements laid off thereupon; this gives all the points taken from that station. After all the side shots are taken, the map may be inked in, provided all possible checks prove that the penciled work is correct. If a topographic map is desired, the stadia sights taken to determine the topography may be located and contours, 10, 20, 25, or 50 ft. apart drawn in. The flatter the country, the smaller should be the contour interval. In ordinary rolling country, where the contours merely serve as a guide to determine the width of pillar in the mine, a contour interval of 25 ft. suffices; in mountainous country, 50 ft. is close enough.

The mine workings are mapped in exactly the same way as the surface features so far as survey lines are concerned, but there is a difference in mapping, as there is in taking, the side shots. On the surface, points are determined by noting their bearing and distance from some station; underground, points are located by offsets at right angles to the line of sight and must be so mapped.

Property corners are marked by a small circle in black and property lines are reasonably heavy ones joining adjacent circles, but not passing within the circumference, the exact corner being a pin point at the center of the circle. On the map should appear the bearing and length of all property lines. A description of the corner should be given as W. O. (for white oak), stone, etc. If the original corner is gone and something else is in place the description should say "W. O., now stone," or "Stone, orig. W. O.," or "Stone (W. O.)," the original corner being placed in parentheses.

The boundaries of all the individual properties making up the entire tract should appear on the map, as well as the name of the owner of each and the acreage. All reservations from under which the coal cannot be mined or to which the company's rights are unusual or peculiar, must be carefully mapped. The names of the owners of adjacent properties should appear. The outcrop of all workable seams should be given in brown, as well as the location of all test openings thereon and the thickness and character of the coal. The position of all oil and gas wells should be accurately determined and mapped, with memoranda as to their operation, production (if any) etc. Abandoned and improperly plugged wells are a constant source of danger in some parts of the country and too much time cannot be spent in accurately locating them. The base-line monuments, together with the azimuth or bearing of the line joining them should be given, as well as all meridian reference lines connected therewith.

Mine workings should be shown in black, the stations being denoted by small circles in the same color. The numbers of all stations and their elevation above sea level should appear. If more than one seam is worked, the

operations in the separate seams should be given a distinctive color, none of which (except the principal workings which may be shown in black) should be used in mapping any surface feature.

When mapping the operations in a single seam, it is not unusual to outline the work done by different colors to represent the extraction during each semi-annual period. Thus, the workings advanced between January 1 and June 30, 1914, would be shown, say, in blue; those from July 1 to December 31, 1914, in red; those from January 1 to June 30, 1915, in green; and similarly for each succeeding period of 6 mo. While this serves to show the extent of the operations for any semiannual period, and this is desirable, it makes an ugly map, and many prefer to plat the mine workings in one single color, drawing a dash across the face of the working places after each semiannual posting has been made. The date, as 6–30–1914, placed by a dash indicates the date at which the posting was made. If many seams are worked under the one property and all are platted on the same sheet, it leads to confusion and it is a better plan not to map them this way, but to make a series of property maps, one for the workings of each seam, or at the most, for the workings of two adjacent seams. Then, if it is desired to note the relationship between the workings of all the seams, a tracing may be made upon which the workings in all the seams are given.

**Coloring a Map.**—The survey line by which the corners were determined is frequently placed on the map in red ink. It is not necessary to give the bearings and distances of the lines, but the stations should be numbered and their elevation above sea level given if this has been determined. Contour lines appear in brown, those marking even hundreds of feet above sea level being heavier than intermediate ones. Small brooks appear as a single line of Prussian blue; larger ones are shown by two parallel lines; and creeks and rivers have their banks shown as they actually exist. If a creek is named, this name should appear on the map. Roads are denoted in brown and should appear in their legal width. Houses are commonly outlined in black, as are tipples, coke ovens, etc. Railroads are denoted by fine parallel lines, marked with black dashes about $\frac{1}{8}$ in. in length; black-and-white dashes of the same length alternating.

It is a question whether it is advisable to tint a map with water colors or not. If the map is a final or finished one upon which no further operations will appear it is advisable to tint it properly; but in the case of a working map, there will be so many erasures as the workings advance, as pillars are drawn, as new lines of railroad are constructed, etc., that the effect of the tinting is soon spoiled. When tinting is used, the inner edge of the property lines should receive a wash in India ink (which will appear in dark gray-black) about $\frac{1}{8}$ in. wide. Crop lines should receive a similar but narrower band in brown. Roads should have a light wash in yellow ocher, and narrow streams, those appearing less than 1 in. in width (100 ft. wide in nature) a light wash in Prussian blue. Large ponds and wide streams if tinted for their full width should be colored with indigo, as the Prussian blue is rather too vivid. Frequently, streams and lakes are not colored for their full width with a flat tint; instead the color is applied with the maximum intensity at the shore line, being gradually drawn out to nothing 1 in. or less therefrom. The projections of houses, barns, tipples, etc., should receive a light wash of crimson lake. Theoretically, unworked areas of coal should be given a flat tint of India ink, the tint being removed to correspond to the mining operations. This is, of course, not practicable, so it is customary to leave the unworked coal, white, and to color the excavations made in mining. As stated, this makes an attractive map when first completed, but as the workings advance and pillars are drawn, the scratching out of previously applied tints, produces an unpleasant effect.

The paper upon which a mine map is made should be the very best eggshell, linen mounted, obtainable. When not in use it, with all other permanent records, should be kept in a fireproof vault.

# DETERMINATION OF MERIDIAN

## LATITUDE AND LONGITUDE

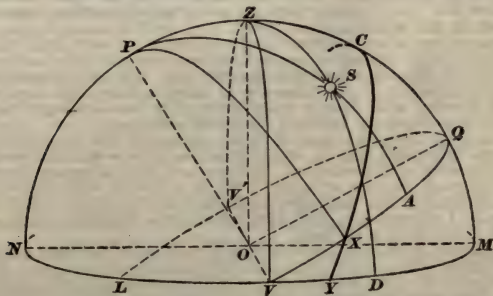
If a meridian, that is, a circle passing through the axis of the earth, is passed through a given point of the earth's surface, the angular distance of the point from the equator, measured on the meridian, is the *latitude* of that point. A plane parallel to the equator cuts the earth's surface in a circle called a *parallel of latitude.* All the points on a parallel of latitude have the same latitude. The *longitude* of a place is the angle that the plane of the meridian of the place makes with the plane of a reference meridian (usually the meridian of Greenwich). This angle may be measured on the equatorial circle or on the parallel of latitude of the given place. Longitude is counted from the reference meridian toward the west.

## CELESTIAL SPHERE

The *celestial sphere* is an imaginary sphere enclosing all the heavenly bodies. It is of such enormous dimensions that, in comparison with it, the earth may be considered as a mere dot. The earth's axis produced indefinitely is called the *axis of the celestial sphere.* This axis intersects the celestial sphere in two points, called the *north pole* and the *south pole* of the heavens. All the great circles of the celestial sphere passing through this axis are called *hour circles.* The circle in which the plane of the equator intersects the celestial sphere is called the *celestial equator.* The point on the equator that the sun in its apparent motion over the celestial sphere crosses on March 21, as it passes from the southern to the northern hemisphere, is called the *vernal equinox.*

## REFERENCE CIRCLES

The accompanying illustration, which represents the celestial hemisphere, shows all the reference circles that are used for determining the position of a heavenly body. *O* is the position of the earth; *OP*, one-half of the axis of the celestial sphere, *P* being the north pole; *VQV'L*, part of the celestial equator; *X*, the vernal equinox; and *YXC*, part of the sun's path. *PX* is the hour circle passing through *X*, called the *equinoctial colure.* *S* is any star, and *PSA* is the hour circle passing through it. *XA* is the *right ascension* of the star,



which is the arc on the equator measured eastwards from the vernal equinox to the hour circle passing through the star. *AS* is the *declination* of the star; that is, its angular distance from the equator. The declination is considered positive when the star is north and negative when south of the equator. The complement angle of the declination, *SP*, is called the *polar distance* of the star.

The *zenith* of a point on the earth's surface is the point *Z* in which the line passing through the center of the earth and the given point intersects the celestial sphere above the given point. The *horizon* is the plane *NYM* passing through the given point and perpendicular to this line.

The *celestial meridian* of a given point is a great circle passing through the zenith of the point and the poles. The celestial meridian cuts the horizon in two points *N* and *M*, called, respectively, the *north point* and the *south point.*

A *vertical circle* is one that passes through the zenith and is perpendicular to the horizon.

The *prime vertical* is the vertical circle at right angles to the meridian; it intersects the horizon in two points $V$ and $V'$, called the *west* and the *east point*, respectively.

The *altitude of a heavenly body* is its angular distance $DS$ from the horizon, measured along the vertical circle passing through the body. The *zenith distance*, is the angular distance $SZ$ of the star from the zenith, measured along the same circle. The zenith distance is the complement of the altitude.

The *azimuth of a star* is the angle in the plane of the horizon intercepted by the planes of the meridian and the vertical circle passing through the star. It is measured from the north point toward the east or from the south point toward the west. $NMD$ is the azimuth of $S$, measured from the north toward the east, and $MD$ is the azimuth of $S$ when measured from the south toward the west.

The *hour angle* of a star is the arc $QA$ intercepted on the equator between the meridian and the foot of the hour circle passing through the star; it is measured from the meridian toward the west.

## TIME

The passing of a heavenly body across the meridian of a place is called its *culmination*, or *transit*. It is upper or lower culmination, according as it is then occupying the highest or the lowest position with regard to the horizon.

The interval of time that elapses between two successive upper or lower transits of a star over the same meridian is called a *sidereal day*. This day begins, for any place, when the vernal equinox crosses the meridian above the pole; this instant is called *sidereal noon*. Sidereal hours, minutes, and seconds are reckoned from 0 to 24 hr., starting from sidereal noon. Time expressed in sidereal days and fractions (hours, minutes, seconds) is called *sidereal time*.

From this, it follows that sidereal time is the hour angle of the vernal equinox; also, that the right ascension of a star is equal to the sidereal time of its transit, or culmination. For any other position of the star, the sidereal time equals the algebraic sum of the right ascension and the hour angle of the star.

The interval between two successive upper transits of the sun is called a *true solar day*, or an *apparent day*. Owing to the fact that the motion of the sun is not uniform and that the solar days are not of equal duration, apparent time is not used for the ordinary affairs of life.

The *mean sun* is an imaginary body supposed to start from the vernal equinox at the same time as the true sun, and to move uniformly on the equator, returning to the vernal equinox with the true sun. The time between two successive upper transits of the mean sun is called a *mean solar day*, and time expressed in mean solar days is called *mean solar time*, or simply *mean time*. This is the time shown by ordinary clocks and watches.

A mean solar day is the mean of the duration of all the true solar days in a year (a year being the time in which either the true or the mean sun makes a complete circuit of the heavens). As there are 365.2422 true solar days and 366.2422 sidereal days in a year. 1 mean solar da. $= 366.2422 \div 365.2422$ $= 1.0027379$ sidereal day $= 24^h \ 3^m \ 56.55^s$, sidereal time.

Likewise, 1 sidereal day $= 365.2422 \div 366.2422 = .99726957$ mean solar day $= 23^h \ 56^m \ 4.09^s$, mean solar time.

The *equation of time* is a certain quantity that must be added algebraically to the apparent solar time to obtain the corresponding mean time. The value of this quantity for each day of the year is given in the American Ephemeris.*

**Civil Time and Astronomical Time.**—By *civil time* is meant the time that is usually reckoned in ordinary life. For astronomical purposes, the day is considered to begin at noon, and hours counted from 0 to 24. When time is reckoned in this manner it is called *astronomical time*. The civil day begins at 12 o'clock at night, and the astronomical day begins 12 hr. later. For instance, the date October 17, $7^h \ 14^m \ 3^s$, astronomical time, means $7^h \ 14^m \ 3^s$ after noon of the civil date October 17, and is in civil time, $7^h \ 14^m \ 3^s$ P. M. The astronomical date February 20, $18^h \ 6^m \ 12^s$ means $18^h \ 6^m \ 12^s$ after noon

---

*The American Ephemeris and Nautical Almanac may be obtained from the Director of the Nautical Almanac, Naval Observatory, Washington, D. C. Remittance must be made in cash or a post-office money order for $1.25. Stamps and checks are not taken.

of the civil date February 20, or 6h 6m 12s after midnight of February 20; that is, February 21, 6h 6m 12s A. M.

**Longitude and Time.**—The mean sun describes a complete circle in 24 mean solar hours. In 1 hr. it moves over $360° \div 24 = 15°$ of arc; in 1 min. of time, over 15' of arc; and in 1 sec. of time, 15" of arc.

**Relation Between Time and Longitude.**—Let $A$ and $B$ be two places on the earth's surface, $B$ being west of $A$. Let their respective longitudes be $h_a$ and $h_b$, and let the difference between $h_a$ and $h_b$, expressed in measure of time, be $d_g$, Let, also, $T_a$ be the time at $A$ when the time at $B$ is $T_b$. Then,

$$T_a = T_b + d_g \qquad (1)$$

and

$$T_b = T_a - d_g \qquad (2)$$

EXAMPLE 1.—The longitude of Washington, west of Greenwich, is 5h 8m 1s; that of San Francisco, 8h 9m 47s. What is the time at: (a) Washington when it is 9h 3m at San Francisco? (b) San Francisco when it is 19h 54m 30s at Washington?

SOLUTION.—(a) Here $A$, the eastern locality, is Washington and $B$ is San Francisco; also, $d_g = $ 8h 9m 47s − 5h 8m 1s = 3h 1m 46s. Therefore, applying formula 1, $T_a = $ 9h 3m + 3h 1m 46s = 12h 4m 46s

(b) Applying formula 2,

$$T_b = 19h\ 54m\ 30s - 3h\ 1m\ 46s = 16h\ 52m\ 44s.$$

**Standard Time.**—Time referred to the meridian of a given place is called the *local time* of that place. To obviate complications in comparing local times of different localities, for use in ordinary affairs of life *standard times* have been adapted for regions between certain longitudes. The United States is divided into four zones, or sections of standard time. The time in each zone is referred to the meridian passing through its center. These central meridians are 15° or 1h distant from one another and are, respectively, 75°, 90°, 105°, and 120° west of Greenwich; or, in hours, 5h, 6h, 7h, and 8h west of Greenwich. Each of these meridians controls the watch time of all places within 7½° on either side. This is shown as follows:

Time referred to the 75° meridian is called *eastern time;* to the 90° meridian, *central time;* to the 105° meridian, *mountain time;* and to the 120° meridian, *Pacific time.*

| | | 8h 30m | 8h | 7h 30m | 7h | 6h 30m | 6h | 5h 30m | 5h | 4h 30m |
|---|---|---|---|---|---|---|---|---|---|---|
| *Pacific* | | *Mountain* | | *Central* | | *Eastern* | | | | |
| 127 30' | 120° | 112 30' | 105° | 97 30' | 90° | 82 30' | 75° | 67 30' | | |

**To Change Standard Time Into Local Time and Vice Versa.**—Standard time can be changed into local time or local time can be changed into standard time by applying formula 1 or formula 2, according as the given place is east or west of the reference meridian of the zone in which the place is located.

EXAMPLE.—The standard time, by a watch, at a place whose longitude is 81° 37', is 9h 37m 45s A. M.; what is the local time?

SOLUTION.—As the longitude is 81° 37', the place lies within the zone of the 75° meridian; and being west of the latter, formula 2 must be applied. In this case, $T_a = $ 9h 37m 45s and $d_g = $ 81° 37' − 75° = 6° 37' = 26m 28s. Therefore, $T_b = $ 9h 37m 45s − 26m 28s = 9h 11m 17s A. M.

## DETERMINATION BY OBSERVING POLARIS AT CULMINATION

The position of Polaris, or the north star, can easily be ascertained by means of the group of stars called the Dipper, or the Great Bear. As shown in the accompanying illustration, a straight line joining the stars, α and β, called the *pointers*, nearly intersects Polaris. There are two times during the day when the star crosses the meridian. It is then said to be at its *upper* or *lower culmination*, as the star is then occupying either the highest or the lowest position with reference to the horizon. When the star is in either of these positions, the vertical plane passing through it and the observer's station is the meridian of the place, and its intersection with the horizon is therefore a true north-and-south line.

**Field Work.**—Select a date on which Polaris is at either lower or upper culmination during the night (preferably during the early part of the evening). Determine, by means of the accompanying table, the exact time of culmination, being careful to reduce the tabular values to standard civil time. It is safer, in order to avoid confusion, for the observer to set his watch to show local time. About 15m before the time of culmination, set the transit in such a position that an unobstructed view toward the north may be obtained for a distance of between 300 and 500 ft. Drive a stake, and mark by a tack the exact point

occupied by the instrument. About 5ᵐ before the time of culmination, direct the telescope to the star, holding a lamp in front and a little toward one side of the objective glass to illuminate the cross-hairs. Set both clamps, and with either tangent screw set the vertical cross-hair exactly on the star. The star will appear to be moving toward the left or toward the right according as it is approaching upper or lower culmination. Follow it in its motion by turning the tangent screw until the exact time of culmination (which, preferably, should be called out by an assistant). This completes the observation of the star. Now depress the telescope, direct it to a point on the ground about 400 or 500 ft. from the instrument, and have an assistant drive a tack in the top of a stake in line with the line of sight; this completes the operation. The line between the two stakes is a true north-and-south line, or true meridian.

**Time of Culmination of Polaris.**—The accompanying table contains the times of upper culmination of Polaris for the dates given. The lower culmination occurs nearly 11ʰ 58ᵐ before and after the upper culmination, and can be determined from the latter. In the table the extreme right-hand column contains the difference between the times of culmination for any two succeeding days. Each difference applies to any day between the date horizontally opposite that difference in the left-hand column, and the following date. Thus, the difference 3.95ᵐ, which is horizontally opposite January 1, indicates that, between January 1 and January 15, the time of culmination decreases by 3.95ᵐ per da. For instance, the time of culmination on January 8 is obtained by subtracting from the time of culmination for January 1 the product 3.95ᵐ×7 =27.65ᵐ, the number of days elapsed from January 1 to January 8 being seven.

It should be borne in mind that the times given in the table are mean local times counted in the astronomical way; that is, from 0ʰ to 24ʰ, beginning at noon.

*Pole* • *Polaris*

*Dipper or Great Bear*

EXAMPLE.—Find the time of upper culmination of Polaris on September 6, 1913.

SOLUTION.—Referring to the table,

Upper culmination, Sept. 1, 1913 . . . . . . . . . . . . . . . . . . = 14ʰ45.3ᵐ
Difference for 1 da . . . . . . . . . . . . . . . . . . . . . . =3.92ᵐ
Correction for 5 da . . . . . . . . . . . . . . . . . . . . =3.92ᵐ×5=   19.6ᵐ
                                                                          _____
Time of culmination on Sept. 6 . . . . . . . . . . . . . . . . . . =14ʰ25.7ᵐ

This means that upper culmination will occur when 14ʰ 25.7ᵐ have elapsed since local noon Sept. 6; that is, at 2ʰ 25.7ᵐ A. M., Sept. 7.

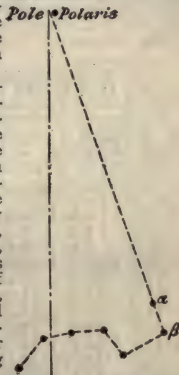
## DETERMINATION BY OBSERVING POLARIS AT ELONGATION

When a star is at its extreme westerly or easterly position, it is said to be at *western* or *eastern elongation.* This position with reference to the meridian of the place is determined by the angle that a vertical plane passing through the star and the point of observation is making with the meridian. This angle is called the *azimuth of the star,* and its values for Polaris, for the years 1913 to 1922 and latitudes 5° to 74°, are given in the accompanying table.

Polaris is at eastern elongation about 5ʰ 55ᵐ before it reaches its upper culmination; and at western elongation, 5ʰ 55ᵐ after upper culmination. The times of elongation can, therefore, be readily determined from those of culmination taken from the table.

EXAMPLE.—Find the time of western elongation of Polaris on March 1, 1914.

SOLUTION.—On referring to the table, it is found that the upper culmination is at 2ʰ 52.5ᵐ, local astronomical time, or 2ʰ 52.5ᵐ, P. M., local civil time. Polaris is at western elongation 5ʰ 55ᵐ later or at 8ʰ 47.5ᵐ, P. M., local civil time.

**Making the Observation and Marking the Meridian.**—Determine the approximate time of elongation as just explained. About 20ᵐ before that time, set the transit over a point properly marked, and level it carefully. Set the vernier at 0. Direct the telescope to the star, and, with both clamps set, follow the star by means of the lower tangent screw. If the star is approaching


eastern elongation it will be moving to the right; if western, to the left. About the time of elongation, it will be noticed that the star ceases to move horizontally, and that its image appears to follow the vertical cross-hair of the instrument. The star has then reached its elongation and the observation is completed. Take the azimuth from the table. Depress the telescope, and turn it through an angle equal to the azimuth, to the west or to the east, according as the star was at eastern or western elongation. The line of sight will then

### AZIMUTHS OF POLARIS AT ELONGATION

be directed along the true meridian, and by marking another point 400 or 500 ft. from that occupied by the instrument, the direction of the true meridian will be established.

This is the most accurate method of determining the true meridian, and, where possible, should be used in preference to others.

As the marking monuments are not commonly set in the meridian, some little change in the method of making the observations from that described is necessary. Having the cross-hair on Polaris at the point of greatest elongation,

the telescope is brought down and the angle between the star and the monument is read. The telescope is inverted and again set on Polaris and the angle to the monument read. This angle may be read four or six times, even more, as the change in position of the pole star for 15ᵐ before and after elongation is not measurable by an ordinary transit. The mean of the two, four, or six readings of the angle is taken as the true angle. By making a sketch of the position of Polaris with reference to the meridian and of the position of the monuments with reference to Polaris, it will be apparent whether the azimuth of the star is to be added to or subtracted from the angle between it and the monuments to give the azimuth of the line joining said reference points. As the determination of the meridian is of great importance it is well, unless the engineer has had experience in the work, to repeat the observations on a second night.

## DETERMINATION BY SOLAR OBSERVATION

**Formula for Azimuth of the Sun.**—One of the most convenient methods of determining the meridian is to measure the altitude of the sun at any hour angle with a transit. At the same time that the altitude is measured, determine, also, the horizontal angle between the sun and a fixed object, or reference mark. Then, the azimuth of the sun is calculated by the formula that follows. The azimuth of the reference mark is then equal to the algebraic sum of the azimuth of the sun and the measured angle between the sun and the mark. Finally, the true north-and-south line may be located from the azimuth of the reference mark.

Let $a$ = required azimuth counted from north toward east;
$z$ = zenith distance of sun, which is equal to 90° minus altitude;
$\delta$ = declination of sun; and
$\phi$ = latitude of observer; then

$$\sin \frac{a}{2} = \sqrt{\frac{\cos \frac{1}{2}(z+\phi+\delta) \sin \frac{1}{2}(z+\phi-\delta)}{\sin z \cos \phi}}$$

Two values of $\frac{a}{2}$ will correspond to the computed $\sin \frac{a}{2}$; one angle will be acute and the other obtuse. The acute angle should be used for morning observations and the obtuse for afternoon observations.

**Values of $\delta$ and $\phi$.**—The method just described requires that the declination of the sun at the time of observation, and the latitude of the place be known. The declination of the sun for every day of the year at the instant of Washington noon, together with the hourly change, is given in the Ephemeris, and has to be reduced to the time of observation as follows:

**Rule.**—*Change the local time to Washington time by adding algebraically to the former the longitude of the place counted from Washington. Take from the Ephemeris the declination corresponding to the preceding Washington noon and add algebraically the product of the hourly change by the time elapsed since Washington noon.*

**Example.**—Find the true declination of the sun for 9 A. M. January 5, 1903, at Philadelphia.

**Solution.**—Jan. 5, 9 A. M., civil time = Jan. 4, 21ʰ, astronomical time. The longitude of Philadelphia is $-7^m 37^s = -.127^h$. The Washington time corresponding to 9 A. M. is $21^h - .127^h = 20.873^h$. From the Ephemeris, the declination at Washington at noon Jan. 4 is $-22° 47' 43''$, and the hourly change is 15.06″. The algebraic increase is, therefore, $15.06 \times 20.873 = 5' 14''$; thus, the declination at 9 A. M. is $-22° 47' 43'' + 5' 14'' = -22° 42' 29''$.

## DETERMINATION OF LATITUDE, AND CORRECTIONS FOR ALTITUDE

**Approximate Determination of Latitude From Polaris.**—In nearly all methods of determining the true meridian, the latitude of the place of observation must be known, at least approximately. In the majority of cases the latitude can be taken from a map or book of reference. In case this cannot be done, a sufficiently close value may be obtained by measuring, with a transit, the altitude of Polaris, which is very nearly (within about 1°) equal to the latitude of the place.

This method of determining latitude is founded on the following very simple and useful principle:

**Principle.**—*The latitude of any place on the earth's surface is equal to the altitude of the pole with respect to the horizon of that place.*

For more accurate work, the tables given in the Ephemeris, entitled, **For Finding the Latitude by Polaris**, may be used. The simple directions for using them are there given in full.

**Latitude by Solar Observation.**—Latitude may be determined by measuring the sun's altitude, with the sextant or transit, at the instant of its passage across the meridian; that is, at apparent noon. The time of apparent noon may be determined by adding algebraically the equation of time to the noon of local mean time, as previously explained. Then begin the observations about 15ᵐ before apparent noon and repeat them every minute or two. At first the altitude will be increasing; then, it will be decreasing. The maximum altitude obtained will be the apparent meridian altitude. To this the corrections that follow must be applied, giving the true altitude. The true altitude is then subtracted from 90°, and the remainder is the zenith distance. The latitude is then equal to the algebraic sum of the zenith distance and the declination of the sun at the instant of apparent noon.

**Corrections for Altitude.**—The observed altitude of a heavenly body must be corrected for: (1) refraction, (2) parallax, and (3) semi-diameter.

1. *Refraction* is the change of direction of the rays of light when they pass from one medium into another of different density. Its amount for different altitudes is given in the table on page 107. It is subtractive. When the altitude is less than about 8° to 10°, the refraction becomes so uncertain that the measurement is of no value for accurate work.

2. *Parallax* is the difference in direction of a heavenly body as actually observed and the direction it would have if seen from the earth's center. This correction is necessary when the sun is observed; its values for different altitudes are given in the accompanying table. It is additive.

## SUN'S PARALLAX IN ALTITUDE TO BE APPLIED TO ALL MEASURED ALTITUDES OF THE SUN
### (Additive to observed altitude)

| Altitude Degrees | Parallax Seconds | Altitude Degrees | Parallax Seconds | Altitude Degrees | Parallax Seconds |
|---|---|---|---|---|---|
| 0 | 9 | 40 | 7 | 69 | 3 |
| 6 | 9 | 45 | 6 | 72 | 3 |
| 12 | 9 | 48 | 6 | 75 | 2 |
| 16 | 8 | 51 | 5 | 78 | 2 |
| 20 | 8 | 54 | 5 | 81 | 1 |
| 25 | 8 | 57 | 5 | 84 | 1 |
| 30 | 8 | 60 | 4 | 87 | 0 |
| 34 | 7 | 63 | 4 | 90 | 0 |
| 36 | 7 | 66 | 3 | | |

3. The correction for *semi-diameter* is also necessary when the sun is observed, owing to the fact that either the upper or the lower edge of the disk, instead of the center, is observed. This correction may be taken from the Ephemeris in the same manner as the sun's declination. For the purpose of ordinary calculations, however, this may be taken from the following table:

| Time of year (approx.)... | Jan. 1, | Apr. 1, | July 1, | Oct. 1 |
|---|---|---|---|---|
| Sun's semi-diameter ..... | 16′ 18″ | 16′ 2″ | 15′ 45″ | 16′ 2″ |

It is additive when the lower limb is observed, and subtractive when the upper one is observed.

**Corrections for Observation of the Sun for Azimuth.**—When the sun is observed for azimuth, a correction for semi-diameter must also be applied to the reading of the horizontal circle; this may be found by dividing the correction for altitude by the cosine of the sun's altitude. This correction is to be added to the reading of the horizontal circle if the hair is placed tangent to the left edge of the sun, and subtracted from the reading of the horizontal circle if the hair is placed tangent to the right edge of the sun.

When making observations of the sun for azimuth, the errors of adjustment, the index error, and the correction for semi-diameter may be eliminated by the following method, which assumes that the vertical circle of the transit is complete:

The instrument is set up with the horizontal plate reading 0° when sighting at the azimuth mark. For forenoon work, the sun should be so sighted that

## MEAN REFRACTION TO BE APPLIED TO ALL MEASURED ALTITUDES

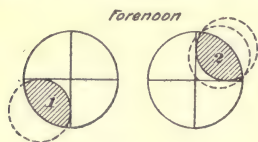
|  |  |  |  | 19 50 | 2 37 | 33 30 | 1 26 | 90 0 | 0 0 |

it occupies position *1*, Fig. 1, with reference to the cross-hairs; the time, vertical angle, and horizontal angle are noted. Then the upper plate is loosened, the instrument turned 180° in azimuth, the telescope inverted, and the sun sighted again, as in position *2*. In position *1*, the sun is moving toward both hairs; in position *2*, the telescope should be set approximately as shown by the dotted circle, so that the sun will clear both hairs at the same instant. For



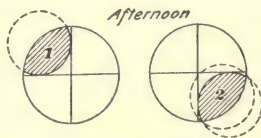


FIG. 1　　　　　　　　　　FIG. 2

afternoon work, the positions shown in Fig. 2 should be used. The observations are taken in *pairs;* if the second observation of a pair cannot be obtained promptly after the first one (owing to a passing cloud, or some other cause), the first must be ignored and considered as useless.

It should be noted that the reversal of the transit between the observations eliminates the index error of the vertical circle, the error of level in the horizontal axis of the telescope, and the error of collimation of the telescope. By sighting in diagonal corners of the field of view and taking the mean of the observations, the corrections (both horizontal and vertical) due to the semi-diameter of the sun are eliminated. To simplify the notes, 180° should be added to (or subtracted from) the horizontal plate reading when the instrument is inverted.

EXAMPLE.—The following measurements were taken in the manner just described. The four means of the circle readings were formed in the field. The declination of the sun was −9° 30′ 5″, and the approximate latitude +39° 57′. Find the azimuth of the reference mark.

| Telescope | Time P. M. | Vertical Circle | | | Horizontal Circle | | |
|---|---|---|---|---|---|---|---|
| Direct | 3:27 | 19° | 39′ | 00″ | 99° | 52′ | 00″ |
| Inverted | 3:29 | 19 | 52 | 00 | 99 | 49 | 00 |
| Mean | 3:28 | 19 | 45 | 30 | 99 | 50 | 30 |
| Direct | 3:32 | 18 | 46 | 00 | 100 | 55 | 30 |
| Inverted | 3:34 | 19 | 3 | 00 | 100 | 49 | 00 |
| Mean | 3:33 | 18 | 54 | 30 | 100 | 52 | 15 |
| Direct | 3:36 | 18 | 4 | 30 | 101 | 46 | 00 |
| Inverted | 3:38 | 18 | 23 | 30 | 101 | 35 | 00 |
| Mean | 3:37 | 18 | 14 | 00 | 101 | 40 | 30 |
| Direct | 3:40 | 17 | 26 | 30 | 102 | 29 | 30 |
| Inverted | 3:42 | 17 | 43 | 00 | 102 | 21 | 00 |
| Mean | 3:41 | 17 | 34 | 45 | 102 | 25 | 15 |

SOLUTION.—

| Mean of the four vertical circle readings | 18° | 37′ | 11″ |
|---|---|---|---|
| Refraction | | −2 | 48 |
| Parallax | | | +8 |
| True altitude of center | 18° | 34′ | 31″ |
| Zenith distance = 90° − true altitude | 71° | 25′ | 29″ |

To find the azimuth of the sun: $z = 71° 25′ 29″$; $\phi = 39° 57′ 0″$; $\delta = -9° 30′ 5″$; $\frac{1}{2}(z + \phi + \delta) = 50° 56′ 12″$; $\frac{1}{2}(z + \phi - \delta) = 60° 26′ 17″$. Substituting these values in the formula for the azimuth of the sun.

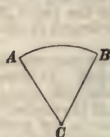
$$\sin \tfrac{1}{2}a = \sqrt{\frac{\cos 50° 56′ 12″ \sin 60° 26′ 17″}{\sin 71° 25′ 29″ \cos 39° 57′}}$$

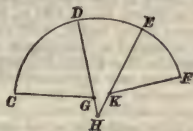
The two values of $\frac{1}{2}a$ are 60° 17′ 15″ and 119° 42′ 45″ ($= 180° - 60° 17′ 15″$). As the observations were made in the afternoon, the obtuse angle should be used. This gives $a = 2 \times 119° 42′ 45″ = 239° 25′ 30″$. The mean of the four horizontal readings is 101° 12′ 8″. Subtracting this from the azimuth of the sun, the azimuth of the reference mark is found to be 239° 25′ 30″ − 101° 12′ 8′ = 138° 13′ 22″.

# RAILROAD SURVEYING

## DEFINITIONS OF CIRCULAR CURVES

The line of a railroad consists of a series of straight lines connected by curves. Each two adjacent lines are united by a curve having the radius





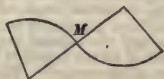


FIG. 1    FIG 2    FIG. 3

best adapted to the conditions of the surface. The straight lines are called *tangents*, because they are tangent to the curves that unite them.

Railroad curves are usually circular and are divided into three general classes, namely, simple, compound, and reverse curves.

A *simple curve* is a curve having but one radius, as the curve $AB$, Fig. 1, whose radius is $AC$.

A *compound curve* is a continuous curve composed of two or more arcs of different radii, as the curve $CDEF$, Fig. 2, which is composed of the arcs $CD$, $DE$, and $EF$, whose respective radii are $GC$, $HD$, and $KE$. In the general class of compound curves may be included what are known as *easement curves*, *transition curves*, and *spiral curves*, now used very generally on the more important railroads.

A *reverse curve* is a continuous curve composed of the arcs of two circles of the same or different radii, the centers of which lie on opposite sides of the curve, as in Fig. 3. The two arcs composing the curve meet at a common point or point of reversal $M$, at which point they are tangent to a common line perpendicular to the line joining their centers. Reverse curves are becoming less common on railroads of standard gauge.

## GEOMETRY OF CIRCULAR CURVES

The following principles of geometry are of special importance as relating to curves:

1. A tangent to a circle is perpendicular to the radius at its tangent point. Thus, in Fig. 4, $AF$ is perpendicular to $BO$ at its tangent point $B$, and $ED$ is perpendicular to $CO$ at $C$.

2. Two tangents to a circle from any point without the circle are equal in length, and make equal angles with the chord joining their points of tangency. Thus, $BE$ and $CE$ are equal, and the angles $EBC$ and $ECB$ are equal.

3. An angle not exceeding 90° formed by a chord and the tangent at one of its extremities, is equal to one-half the central angle subtended by the chord. Thus, the angle $EBC = ECB = \frac{1}{2} BOC$.

4. An angle not exceeding 90° having its vertex in the circumference of a circle and subtended by a chord of the circle, is equal to one-half the central angle subtended by the chord. Thus, the angle $GBH$, whose vertex $B$ is in the

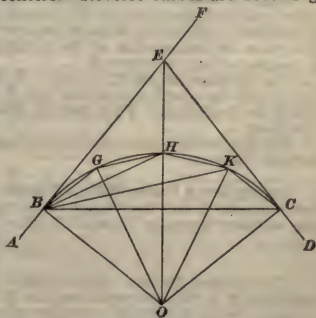

FIG. 4

circumference, is subtended by the chord *GH* and is equal to one-half the central angle *GOH*, subtended by the same chord *GH*.

5. Equal chords of a circle subtend equal angles at its center and also in its circumference, if the angles lie in corresponding segments of the circle. Thus, if *BG*, *GH*, *HK*, and *KC* are equal, *BOG = GOH*, *GBH = HBK*, etc.

6. The *angle of intersection FEC* of two tangents of a circle is equal to the central angle subtended by the chord joining the two points of tangency. Thus, the angle *CEF = BOC*.

7. A radius that bisects any chord of a circle is perpendicular to the chord.

8. A chord subtending an arc of 1° in a circle having a radius = 100 ft. is very closely equal to 1.745 ft.

## ELEMENTS AND METHODS OF LAYING OUT A CIRCULAR CURVE

The *degree of curvature* of a curve is the central angle subtending a chord of 100 ft. Thus, if, in Fig. 4, the chord *BG* is 100 ft. long and the angle *BOG* is 1°, the curve is called a *one-degree curve;* but if, with the same length of chord, the angle *BOG* is 4°, the curve is called a *four-degree curve.*

The *deflection angle* of a chord is the angle formed between any chord of a curve and a tangent to the curve at one extremity of the chord. It is equal to one-half the central angle subtended by the chord. The deflection angle for a chord of 100 ft. is called the *regular deflection angle*, and is equal to one-half the degree of curvature. The deflection angle for a *subchord*—that is, for a chord less than 100 ft.—is equal to one-half the degree of curvature multiplied by the length of the subchord expressed in chords of 100 ft. The length *c* of a subchord or of any chord is given by the formula

in which
$$c = 2R \sin D$$
$R$ = radius;
$D$ = deflection angle of that chord.

**Relation Between Radius and Deflection Angle.**—From the formula just given,

$$R = \frac{c}{2 \sin D}$$

If $D_{100}$ is the deflection angle for a chord of 100 ft., then

$$R = \frac{50}{\sin D_{100}}$$

For a 1° curve, $D_{100} = 30'$ and $R = 5,730$, nearly. For curves less than 10°, the radius may be taken as $\frac{5,730}{D_c}$, in which $D_c$ is the degree of curvature. The accompanying table gives the length of the radius, in feet, for degrees of curvature ranging by intervals of 5' and 10' from 0' to 20°.

**Tangent Distance.**—The point where a curve begins is called the *point of curve*, and is designated by the letters P. C.; and the point where the curve terminates is called the *point of tangency*, and is designated by the letters P. T. The point of intersection of the tangents is called the *point of intersection;* it is designated by the letters P. I.

The distance of the P. C. or P. T. from the P. I. is called the *tangent distance*, and the chord connecting the P. C. and P. T. of a curve is commonly called its *long chord*. This term is also applied to chords more than one station long.

If *I* denotes the angle of intersection and *R* the radius of the curve, then the tangent distance

$$T = R \tan \tfrac{1}{2}I$$

**Laying Out a Curve With a Transit.**—When the angle of intersection *I* has been measured and the degree of curve decided upon, the radius of the curve can be taken from the Table of Radii and Deflections or it can be figured by the formula

$$R = \frac{5,730}{D_c}$$

The tangent distance is then computed and measured back on each tangent from the P. I., thus determining the P. C. and P. T. Subtracting the tangent distance from the station number of the P. I. will give the station number of the P. C. Ordinarily, this will not be an even or full station. The length of the curve is then computed by dividing the angle *I* by the degree of curve, the quotient giving the length of the curve in stations of 100 ft. and decimals thereof. After having found the length of the curve, compute the deflection angles for the chords joining the P. C. with all the station points; set the transit at the P. C.; set the vernier at 0, sight to the intersection point, and turn off

## TABLE OF RADII AND DEFLECTIONS

| Degree | Radii | Chord Deflection | Tangent Deflection |
|---|---|---|---|
| 0° 05′ | 68,754.94 | .145 | .073 |
| 0° 10′ | 34,377.48 | .291 | .145 |
| 0° 15′ | 22,918.31 | .436 | .218 |
| 0° 20′ | 17,188.76 | .582 | .291 |
| 0° 25′ | 13,751.02 | .727 | .364 |
| 0° 30′ | 11,459.19 | .873 | .436 |
| 0° 35′ | 9,822.18 | 1.018 | .509 |
| 0° 40′ | 8,594.49 | 1.164 | .582 |
| 0° 45′ | 7,639.49 | 1.309 | .654 |
| 0° 50′ | 6,875.55 | 1.454 | .727 |
| 0° 55′ | 6,250.51 | 1.600 | .800 |
| 1° 00′ | 5,729.65 | 1.745 | .873 |

successively the deflection angles, at the same time measuring the chords and marking the stations. The station of the P. T. is found by adding the length of curve in chords of 100 ft. to the station of the P. C.

FIG. 1

If the entire curve cannot be run from the P. C. on account of obstructions to the view, run the curve as far as the stations are visible from the P. C. and run the remainder of the curve from the last station that can be seen. Suppose that in the 10° curve shown in Fig. 1 the station at $H$, 200 ft. from the P. C., is at $B$, is the last point on the curve that can be set from the P. C. A plug is driven at $H$ and centered carefully by a tack driven at the point. The transit is now moved forward and set up at $H$. As the deflection angle $EBH$ is 10° to the right, an angle of 10° is turned to the left from 0 and the vernier clamped. The instrument is then sighted to a flag at $B$, the lower clamp set, and by means of the lower tangent screw the cross-hairs are made to bisect the flag exactly. The vernier clamp is then loosened, the vernier set at 0, and the telescope plunged. The line of sight will then be on the tangent $IP$, and the deflection angles to $K$ and $C$ can be turned off from this tangent, and the stations at $K$ and $C$ located in the same manner that the stations at $G$ and $H$ were located from $B$, because the angle at $IHB$ between the tangent $IH$ and the chord $BH$ is equal to the angle $EBH$ between the tangent $EB$ and the same chord.

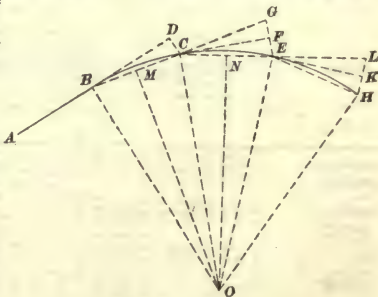
This method of setting the vernier for the backsight when the instrument is moved forwards to a new instrument point on the curve is sometimes called the *method by zero tangent*. The essential principle of the method is that the vernier always reads zero when the instrument is sighted on the tangent to the curve at the point where the instrument is set, and the deflection angles are made to read from the tangent to the curve at this point in the same manner as if this point were the P. C. of the curve.

**Tangent and Chord Deflections.**—Let $AB$, Fig. 2, be a tangent joining the curve $BCEH$ at $B$. If the tangent $AB$ is prolonged to $D$, the perpendicular distance $DC$ from the tangent to the curve is called a *tangent deflection*. If the chord $BC$ is prolonged to the point $G$, so that $CG = CE$, the distance $GE$ is called a *chord deflection*. If the radius $R$ of the curve and the length of the chord $c$ are known, the tangent deflection $f$ can be determined by the formula

$$f = \frac{c^2}{2R}$$

This formula can be used for any length of chord or radius. If $CE = BC$, the chord deflection $= 2f = \frac{c^2}{R}$. For this condition the Table of Radii and Deflections gives the chord deflection and tangent deflection for 100-ft. chords and for degrees of curvature varying by intervals of 5′ and 10′ from 5′ to 20°.

FIG. 2

When the two chords preceding the station considered are of unequal lengths, the chord deflection $= \frac{c_1(c_1 + c_2)}{2R}$, where $c_1$ is the length of the first chord


and $c_2$ the length of the second chord preceding the station considered. When the tangent deflection $f$ is known, the chord deflection

$$d_0 = f\left(1 + \frac{c_2}{c_1}\right)$$

**Special Values of Chord and Tangent Deflection.**—For a chord of 100 ft. preceded by one of the same length the chord deflection for a 1° curve is 1.745; for a 2° curve, it is twice that amount, or 3.49; and so on. The tangent deflection, being half the chord deflection, will be .873 ft. for a 1° curve, 1.745 for a 2° curve, etc. The tangent deflection for a chord of any length equals the tangent deflection for a chord of 100 ft. multiplied by the square of the given chord expressed as the decimal part of a chord of 100 ft.

**Application of Chord and Tangent Deflection.**—Let it be required to restore center stakes on the 4° curve, Fig. 3, at each full station. The points $A$ and $B$ determine the direction of the tangent, the point $B$ being the P. C., which is at Sta. 8+25. For a 4° curve the regular chord deflection for 100 ft. is $4 \times 1.745 = 6.98$ ft., and the tangent deflection is 3.49 ft. The distance from P. C. to the next full station is 75 ft.; hence, the tangent deflection $CF = .75^2 \times 3.49 = 1.96$ ft. The point $F$ is found by first measuring 75 ft. from $B$, thus locating the point $C$ in the line $AB$ prolonged, then from $C$ measuring $CF = 1.96$ ft., at right angles to $BC$; the point $F$ thus determined will be Sta. 9. Next, the chord $BF$ is prolonged 100 ft. to $D$; $BF$ is only 75 ft.; $DG$ is computed from the preceding formula; thus, $d_0 = 3.49 (1 + \frac{75}{100}) = 6.11$. This distance is measured at right angles to $BD$; the point $G$ thus determined will be Sta. 10. The point $H$, which is Sta. 11, and the P. T. of the curve, is determined in the same manner, except that, as the chords $FG$ and $GH$ are each 100 ft. long, the regular

Fig. 3

chord deflection of 6.98 ft. is used for $EH$. A stake is driven at each station thus located. Although a chord deflection is not at right angles to the chord theoretically, yet the deflection is so small, as compared with the length of the chord, that for curves of ordinary degree it is usually measured at right angles.

**Middle Ordinate.**—The *middle ordinate* of a chord is the ordinate to the curve at the middle point of the chord. The following formulas give the relation between the length of the chord $c$, the radius of the curve $R$, and the middle ordinate $m$.

$$m = R - \sqrt{R^2 - \frac{c^2}{4}}$$

$$c = 2\sqrt{2Rm - m^2}$$

$$R = \frac{c^2}{8m} + \frac{m}{2}$$

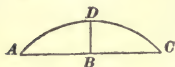
**To Determine Degree of Curve From Middle Ordinate.**—It is sometimes necessary to determine the radius or the degree of a curve in an existing track when no transit is available. By measuring the middle ordinate of any convenient chord, the degree of the curve can be calculated from the relative values of the ordinate and chord. As the track is likely not to be in perfect alinement, it is well to measure the middle ordinate of different chords in different parts of the curve; also, as the middle ordinate of a chord measured to the inner rail will somewhat exceed the middle ordinate of the same chord measured to the outer rail, the ordinate of each chord should be measured to both rails and the average of the two taken as the value of the ordinate. Having measured the middle ordinate of one or more chords, the degree of curve $D_c$ can be found by the formula

$$D_c = \frac{45,840 \, m}{c^2}$$

The following rule is sometimes applied in determining the degree of curve:
**Rule.**—*Measure the middle ordinate to a chord of 67.71 ft.; express it in feet and decimals of a foot, and multiply by 10; the result will be the degree of the curve.*

**Rules for Measuring the Radius of a Curve.**—Stretch a string, say 20 ft. long, or longer if the curve is not a sharp one, across the curve corresponding

FIG. 4

to the line from $A$ to $C$, in Fig. 4. Then measure from $B$ the center of the line $AC$, and at right angles with it, to the rail at $D$. Multiply the distance $A$ to $B$, or one-half the length of the string, in inches, by itself; measure the distance $D$ to $B$ in inches, and multiply it by itself. Add these two products, and divide the sum by twice the distance from $B$ to $D$, measured exactly in inches and fractional parts of inches. This will give the radius of the curve in inches.


It may be more convenient to use a straightedge instead of a string. Care must be taken to have the ends of the string or straightedge touch the same part of the rail as is taken in measuring the distance from the center. If the string touches the bottom of the rail flange at each end, and the center measurement is made to the rail head, the result will not be correct.

In practice, it will be found best to make trials on different parts of the curve, to allow for irregularities.

ILLUSTRATION.—Let $AC$ be a 20-ft. string; half the distance, or $AB$, is then 10 ft., or 120 in. Suppose $BD$ is found on measurement to be 3 in. Then $120 \times 120 = 14,400$, and $3 \times 3 = 9$; $14,400 + 9 = 14,409$, which, divided by $2 \times 3 = 6$, equals $2,401\frac{1}{2}$ in., or 200 ft. $1\frac{1}{2}$ in., which is the radius of the curve. The formula $\dfrac{AB^2 + BD^2}{2\,BD} = R$, applied to the example is

$$\frac{120^2 + 9}{2 \times 3} = 2,401\tfrac{1}{2} \text{ in.} = 200 \text{ ft. } 1\tfrac{1}{2} \text{ in.}$$

**Other Ordinates.**—Any ordinate $y$ to the curve at a distance $a$ from the middle point of a chord may be determined by means of the formula:

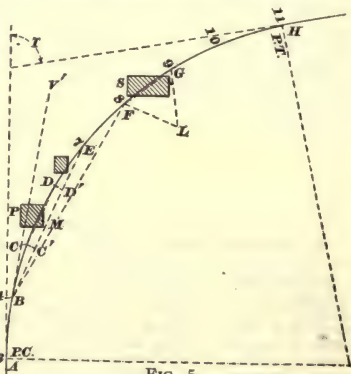
$$y = \sqrt{R^2 - a^2} - R + m$$

By using long chords, a curve may be laid out or obstacles passed by means of ordinates. Suppose that it is required to run out the curve $AEH$, Fig. 5, with several obstacles in the direct line of the curve, as shown, Sta. 3 being the P. C., and the regular stations on the curve being in the positions indicated by the numbers 4, 7, 8, etc. The positions of Stas. 5 and 6 are indicated by the letters $C$ and $D$. The stations are to be located in their proper positions on the curve, between the obstructions, wherever it is possible to do so. In addition to this, it is customary to mark with a tack or otherwise the point where the line of the curve intersects each obstruction.

Beginning at the point of curve $A$, which is at Sta. 3, the curve can be run in as far as the first obstruction, which is the building $P$, setting the stakes on the curve at Stas. 4 and 5, and a tack in the side of the building $P$ at the point where the line of curve intersects, according to the deflection angle as determined by its distance from Sta. 5. It is not possible to proceed further in the regular manner, however, because Sta. 6 cannot be seen from the P. C. Therefore, it is necessary to locate Sta. 7 by deflection angle $V'BE$, from $B$ or Sta. 4, to determine the chord 4–7, which, in this case, is a long

FIG. 5

chord of three stations, and to calculate the ordinates $D'D$ and $C'C$ by substituting for $a$ in the preceding formula the value of $MC' = MD' =$ half a station or 50 ft.

Fig. 5 shows also another method of passing a building $S$, namely, by running an equilateral triangle $FLG$. In this method, the instrument is set up at Sta. 8 and sighted back to the P. C. Then, the telescope is reversed and the deflection angle for Sta. 9 is turned off the same as if no obstruction existed.


The telescope will then be sighted on the line $FG$, although the point $G$ will not be visible. The angle $GFL$, equal to 60°, is then turned, and the point $L$ is located so that $FL = FG = 100$ ft. The instrument is next moved to $L$, and the line $LG$ is run, making 60° with $FL$. On this line the distance $LG = 100$ ft. is measured, giving the point $G$, which is Sta. 9. The transit is then set up at this point and sighted to $L$, and an angle of 60° is turned off to the right, giving the direction of the line 9–8, the intersection of which with $S$ is marked. The remainder of the curve may be run in the following manner: Set the vernier at an angle equal to the deflection angle of the chord 9–8 to the left from the 0; clamp the upper plate, sight at the point set in the line 9–8; then clamp the lower plate and set vernier at 0. The line of sight will then be in the tangent at point 9, and by plunging the telescope the remainder of the curve can be run as if the point 9 were the P. C.

## FIELD NOTES FOR CURVES

Various styles of field notebooks are published, in which the pages are ruled to suit the different kinds and methods of field work. The accompanying, which are the field notes of a portion of a line containing a curve, represent a good form for recording the field notes of a curve that is run in by the method of zero tangent.

In the first column are recorded the station numbers; in the second column, the deflections with the abbreviations P. C. and P. T., together with the degree of curve and the abbreviation R or L, according as the line curves to the right or left. At each transit point on the curve, the total or central angle from the P. C. to that point is calculated and recorded in the third column. This total angle is double the deflection angle between the P. C. and the transit point. In

| Station | Deflection | Tot.Angle | Mag.Bearing | Ded.Bearing | Remarks | June 20.1912 |
|---------|-----------|-----------|-------------|-------------|---------|---------|
| 9 | | | | | | |
| 8 | - | | | | | |
| 7 | | | | | | |
| 6+95 | 4°54′P.T. | 15°00′ | N35°20′E. | N35°15′E. | | |
| 6+50 | 4°00′ | | | | | |
| 6 | 3°00′ | | | | | Centerline of highway |
| 5+50 | 2°00′ | | | | 5+80 | |
| 5 | 1°00′ | | | | 5+60 | |
| 4+50 | 2°36′ | 5°12′ | | | | |
| 4 | 1°36′ | | | | Int.Angle=15°00′ | 4°Curve R |
| 3+50 | 0°36′ | | | | T=188.61 ft. | Def.Angle for 50 ft.=1°00′ |
| 3+20 | P.C.4°R. | | | | P.C.=3+20 | Def.Angle for 1 ft.=1.2′ |
| 3 | | | | | Length of Curve=375 ft. | |
| 2 | | | | | P.T.=6+95 | |
| 1 | | | | | | |
| 0 | | | N20°15′E. | N20°15′E. | | |

these notes, there is but one intermediate transit point between the P. C. and the P. T. The deflection from the P. C. at Sta. 3+20 to the intermediate transit point at Sta. 4+50 is 2° 36′. The total angle is double this deflection, or 5° 12′, which is recorded on the same line in the third column. The record of total angles at once indicates the stations at which transit points are placed. The total angle at the P. T. will be the same as the angle of intersection, provided the work is correct. When the curve is finished, the transit is set up at the P. T., and the bearing of the forward tangent taken, which affords an additional check upon the previous calculations. The magnetic bearing is recorded in the fourth column, and the deduced, or calculated, bearing is recorded in the fifth column.

## EARTHWORK

**Cuts and Fills.**—When building a railroad, cuts and fills are introduced to equalize the irregularities of the natural soil. Figs. 1 and 2 show a typical fill and cut in ordinary firm earth or gravel.

**Slope Ratio.**—In cuts in the hardest rock, the average slope is made usually $\frac{1}{4}$:1; that is, $\frac{1}{4}$ horizontal to 1 vertical. As the soil becomes less firm, the slope must be flattened until, for a soil of firm earth or gravel, a slope of 1 to 1 may be permissible, although a slope of $1\frac{1}{2}$:1 is commonly adopted. In very soft soil, the slope ratio is sometimes cut down even as far as 4 horizontal to 1 vertical.

The standard practice in a fill is 1½ horizontal to 1 vertical. When a fill is made of the material from a rock cut, it is possible to make a stable embankment with a slope ratio of 1:1. On side-hill work, where a slope ratio of 1¼:1 or even 1:1 might require a very long slope, it is often advisable to make a rough dry wall of the stones from a rock cut that will have a slope ratio of ¾:1, or it may even be steeper.

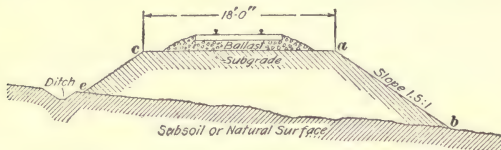


FIG. 1

**Width of Excavations and Embankments.**—The width required for a standard-gauge single-track roadbed may be estimated as follows (see Figs. 1 and 2): The tie will be between 8 and 9 ft. long, usually 8 ft. 6 in., and at the ends the ballast will slope down to subgrade. The extra width required for this will be about 1 or 2 ft. at each end of the tie. Usually, the embankment is widened for about 2 ft. beyond the ballast on each side. The absolute minimum for the width of subgrade for a fill is, therefore, 8½ ft. + 2 × (1 + 2) ft. = 14½ ft. This width would be used only for light-traffic, cheaply constructed roads; 16 to 18 ft. is far more common, while 20 ft. and even more is frequently used, as the danger of accident due to a washing out of the embankment is materially reduced by widening the roadbed.

In cuts, the proper width for two ditches should be added. Unless the soil is especially firm, the ditches should have a side slope of 1½:1. If the ditch is 12 in. wide at the base and 12 in. deep, with side slopes of 1½:1, each ditch will require a total width of 4 ft. This will add 8 ft. to the width of the cut at the elevation of subgrade. The usual distance between track centers for double track is 13 ft. Therefore, whatever rate of side slopes and width of ditches is required for single-track work, the width for double-track work must be 13 ft. greater. When excavation is made through rock, the side slopes of the ditches may properly be made much steeper; the danger of scouring during heavy rain storms being eliminated, the total required width may be very materially reduced from the figures just given. The heavy expense of excavating through solid rock requires that such economy shall be used if possible.

**Grade Profile.**—For the purpose of constructing a road as well as for calculating the earthwork, a grade profile is prepared by setting stakes on the center line at every full station and also at all intermediate points at which the inclination of the natural surface of the ground changes abruptly; then, by leveling, the elevation of the natural surface at each stake is determined and plotted, as explained under Leveling. The established grade is then drawn in.

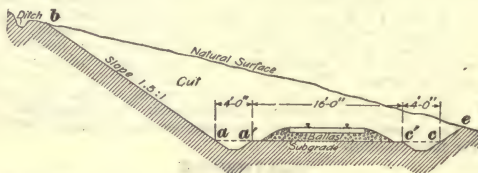

FIG. 2

It consists of a series of straight lines, the elevations of the ends of which are clearly indicated. These elevations are those of the subgrade *ac*, Figs. 1 and 2.

A short portion of a profile is shown in Fig. 3. The horizontal line *XX'* represents a reference plane, and the broken line *AGH* shows the position of the established grade. The station numbers are written along the line *XX'*, and the elevations of the corresponding points of the established grade are

written along the grade line. Thus, in Fig. 3, the elevation of subgrade at Sta. 90, or *A*, is 100 ft.; at Sta. 93, or *G*, it is 102.28 ft.; and at Sta. 94, or *H*, it is 101.78 ft.

The *gradient* of the established grade is the per cent. of rise or fall of grade; that is, the number of feet by which the elevation increases or decreases in 100 ft. It is usually marked on the grade line in the manner shown in Fig. 3.

The *depth of center stake* is the difference between the elevation of the

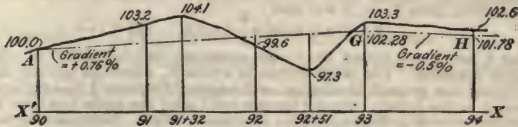

FIG. 3

natural surface at any stake and the elevation of the subgrade. The elevation of the natural surface is found in the level notes, while the elevations of the subgrade are computed from the gradients and also entered in the level notes. The difference for each stake is then figured and entered in a column headed Depth of Center Stake, being preceded by the letter *C* or *F* to indicate cut or fill.

EXAMPLE.—Stakes are set at the stations indicated in the first column of the accompanying field notes. The gradient is +.76% from Sta. 90 to Sta. 93, and −.50% beyond Sta. 93. The elevation of the established grade at Sta. 90 is 100 ft.; the elevation of the natural surface at each stake is given in the third column. Find the center depth at each stake. (See Fig. 3.)

| Station | Subgrade | Elevation | Depth of Center Stake |
|---|---|---|---|
| 94 | 101.8 | 102.6 | C .8 |
| 93 | 102.3 | 103.3 | C 1.0 |
| 92+51 | 101.9 | 97.3 | F 4.6 |
| 92 | 101.5 | 99.6 | F 1.9 |
| 91+32 | 101.0 | 104.1 | C 3.1 |
| 91 | 100.8 | 103.2 | C 2.4 |
| 90 | 100.0 | 100.0 | 0 |

SOLUTION.—The elevations of the subgrade at the station stakes are determined as follows:

| Station | Elevation |
|---|---|
| 91 | $100.00 + 1.00 \times .76 = 100.8$ |
| 91+32 | $100.00 + 1.32 \times .76 = 101.0$ |
| 92 | $100.00 + 2.00 \times .76 = 101.5$ |
| 92+51 | $100.00 + 2.51 \times .76 = 101.9$ |
| 93 | $100.00 + 3.00 \times .76 = 102.3$ |
| 94 | $102.28 + 1.00 \times -.50 = 101.8$ |

The center depth is the difference between the corresponding numbers in the second and third columns. This is a fill if the subgrade is higher than the natural surface; otherwise, it is a cut.

**Slope Stakes.**—In addition to center stakes, slope stakes are used to mark the points where the side slopes of a cut or a fill intersect the natural surface of the ground. In Fig. 4, *c* is the center stake and *m* and *m'* are the slope stakes. The method of locating slope stakes is as follows, all letters referring to Fig. 4:

Let *b* be the width *l l'* of the roadbed; *d*, the depth *ce* of the center stake; and *s* the slope ratio $= lk \div mk = l'k' \div m'k'$. For the upper stake at *m*, let *x* be the distance *mq* from the slope stake to the center line; $y + d$, the elevation of *m* above the subgrade $= qc + ce = mk$. Similarly for the lower stake at *m'*,

let $x'$ be the horizontal distance $m'q'$ from $m'$ to the center line, and let $d-y'$ $=m'k'$, the elevation of $m'$ above the subgrade.

Then,
$$x=\frac{b}{2}+s\times d+s\times y \qquad (1)$$

and
$$x'=\frac{b}{2}+s\times d-s\times y' \qquad (2)$$

If the natural surface $mcm'$ is a level line, so that $q$, $c$, and $q'$ are at the same elevation, then $y=o$, $y'=o$, and
$$x=x'=ca=ca'=\frac{b}{2}+s\times d \qquad (3)$$

Formulas 1 and 2 are called *slope-stake equations* and formula 3 is called the *level-section equation.* The last formula is available when the ground is nearly level. When the ground is sloping or irregular, formula 1 is employed, but not directly, as the value of $y$ is not known until after the stake has been located. The distance $x$ or $x'$ is determined by successive trials. Suppose, for example, that, in Fig. 4, $d=6.3$ and the rod reading on the point $c$ be 5.9. Suppose, also, that $s=1.5:1$. Then, if the ground is level, by formula 3,

$$ac=\frac{20}{2}+1.5\times6.3=19.5 \text{ ft.}$$

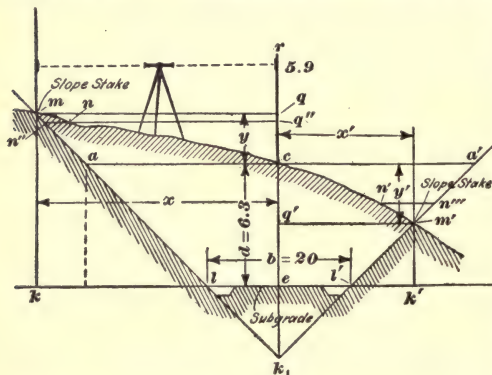
To find the location of $m$, the rodman will hold the rod at some point more than 19.5 ft. from $cr$. Suppose that he holds it at $n$, 20 ft from $cr$, and that the

reading on the rod in this position is 2.8. Then, the height of this point above $c$ equals the reading on $c$ minus the reading on $n$, or 5.9 − 2.8 = 3.1 ft. The computed distance from the rod to $cr$ is, by formula 1, $\frac{20}{2}$ + 1.5 × 6.3 + 1.5 × 3.1 =24.2 ft. As the measured distance (20 ft.) is much smaller than this, the rod must be moved much farther out.

FIG. 4

Suppose that the rod is carried out 7 ft. so that the measured distance to $cr$ is 27 ft., and suppose that the reading on the rod in this position is .8 ft. The elevation of this trial point above $c$ will be 5.9−.8=5.1 ft., and by formula 1, the computed distance $x$ is $\frac{20}{2}$+1.5×6.3+1.5×5.1=27.2 ft. This agrees so closely with the measured distance that the slope stake may be driven at this point.

The lower slope stake at $m'$ is set in the same manner as the upper, except that the distance of each trial point below $c$ is measured, and formula 2 is used in computing the corresponding value of $x'$. The distance of the trial point from $cr$ will in this case be taken less than the distance $ca'$ computed by formula 3. As in the preceding case, if the measured distance from $cr$ to the trial point is less than the computed distance, the point should be moved out; if greater, it should be moved in.

**Form of Notes in Cross-Section Work.**—When each slope stake has been set as just explained, its distance from the center line and the elevation of the stake above or below subgrade are entered in the field book in the form of a fraction. The numerator of this fraction is the distance of the stake above or below subgrade, and the denominator is the distance of the stake from the center line. Thus, if the slope stakes in the preceding example are set at Sta. 131, the complete entry in the notebook will be as follows:


| Station | Subgrade | Elevation | Center Depth | Left | Right |
|---------|----------|-----------|--------------|------|-------|
| 132 | 149.80 | 159.7 | C 9.9 | C 11.4 | C 2.3 |
| 131 | 148.80 | 155.1 | C 6.3 | 27.2 | 13.5 |
| 130 | 147.80 | 147.2 | F .6 | | |

The fraction $\dfrac{C11.4}{27.2}$ indicates that the left slope stake at *m*, Fig. 4, is 27.2 ft. from the center line of the roadbed and 11.4 ft. above subgrade. Similarly, the fraction $\dfrac{C2.3}{13.5}$ indicates that the right slope stake *m'* is 13.5 ft. to the right of the center line and 2.3 ft. above subgrade. These expressions are called *slope-stake fractions*.

When the ground between the slope stakes and the center stake is irregular, the elevations and distances from the center of the intermediate points where the ground changes abruptly are determined and also entered in the notebook in the form of fractions.

## RAILROAD LOCATION

The preliminary survey is made by the methods given, a random line being run along the proposed route and a map of the region made covering several hundred feet on each side of the traverse. The map should show both banks of any streams and enough levels should be taken to show the contours within the width covered by the map. This width will depend on the nature of the ground, being less in hilly than in flat country. In general, the map should cover the ground from the toe of one side hill to the toe of the other and should extend a distance up each hill to an elevation beyond which it would not be practicable to make a cut. After this preliminary line has been mapped, a preliminary estimate of the cost of the proposed work may be made.

**Preliminary Estimate.**—When making a preliminary estimate, great accuracy is not necessary, and no time should be wasted in useless refinements of calculation. The estimate should be high enough to cover all probable cost, and a liberal allowance should be made to cover unforeseen contingencies that may develop during construction. Most experienced engineers make it a rule to add 10% to a preliminary estimate in order to provide for contingencies.

When estimating for earthwork, the cross-sections may be considered as level cuttings; that is, the cross-section surface may be considered as level, unless its slope angle exceeds 10°, in which case a suitable allowance must be made for the slope. The preliminary estimate, which also includes approximate figures for material and labor required for culverts, bridges, trestles, piers, and abutments is then classified and summarized. A sample of a good form of a preliminary estimate of the cost of a proposed railroad follows:

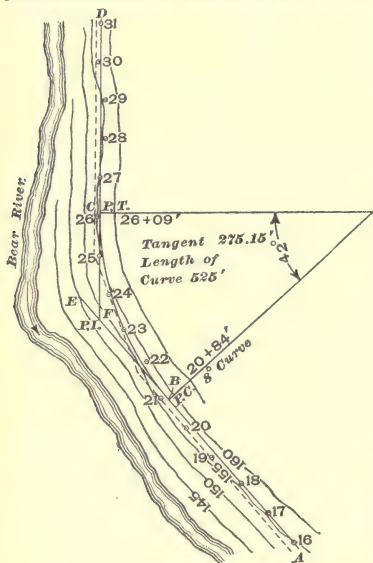
### Estimate of Cost—A & B Railroad

| | |
|---|---:|
| Clearing 625 A. at $20 per A. | $ 12,500 |
| Earth excavation: 900,000 cu. yd. at 17c. | 153,000 |
| Loose-rock excavation: 300,000 cu. yd. at 40c. | 120,000 |
| Solid-rock excavation: 200,000 cu. yd. at 80c. | 160,000 |
| Overhaul exceeding 600 ft.: 300,000 cu. yd. at 1c. | 3,000 |
| Borrowed embankment: 80,000 cu. yd. at 17c. | 13,600 |
| Piling: 12,000 lin. ft. at 25c. | 3,000 |
| Framed trestles: 300,000 ft. B. M. at $35 per M. | 10,500 |
| First-class masonry: 2,800 cu. yd. at $12 | 33,600 |
| Second-class masonry: 4,200 cu. yd. at $8. | 33,600 |
| Box culvert masonry: 2,300 cu. yd. at $5 | 11,500 |
| Dry-rubble masonry: 2,600 cu. yd. at $4. | 10,400 |
| Concrete masonry: 3,000 cu. yd. at $6. | 18,000 |
| Riprap: 2,000 sq. yd. at $1.50. | 3,000 |
| Cast-iron pipe culverts: 40,000 lb. at 3c. | 1,200 |
| Vitrified pipe culverts: 1,800 lin. ft. at $1.50. | 2,700 |
| Total, exclusive of bridges and track. | $589,600 |
| Add 10 per cent. | 58,960 |
| Total cost for grading and trestles. | $648,560 |

**Location.**—The location is the operation of fitting the line to the ground in such a manner as to secure the best adjustment of the alinement and grade, consistent with an economical cost of construction. It is then best projected on the map, and it is called a *paper location*.

FIG. 1

An example of such location is illustrated in Fig. 1. Here, the line follows the valley of Bear River, and the gradient is determined by the slope of the stream. The gradient adopted is .5%, or .5 ft. per station. The preliminary line is shown dotted, and the located line is drawn full.

Let the grade elevation for Sta. 16 be 155 ft.; the grade elevation for Sta. 17 will, therefore, be 155 ft. + .5 ft. = 155.5 ft. The grade elevation for Sta. 18 will be 155.5 + .5 = 156 ft. By the same process, the grade elevation is found for each station shown in the plat; and by means of interpolation between two contour curves, points having the required elevation are located opposite the corresponding stations of the preliminary survey. Each point is marked by a small dot enclosed in a circle. A line joining the points thus designated will be the *grade contour*, or the line where the required gradient meets the surface of the ground. The tangents *AB* and *CD* are then projected so as to conform as closely as practicable to the grade contour, and a suitable curve is inserted for the intersection angle *EFD*. This is most conveniently done by means of a *curved protractor*, an illustration of which is shown in Fig. 2. This instrument, which is made of transparent material, is shifted until there is found a curve that will fit the topography and will close the angle between the tangents, as required.


**Curvature.**—There is no fixed rule for limiting curvature, but for a permanent track it is desirable to have the curvature as easy as possible. For all ordinary traffic conditions, it is good practice to use such curves as will best conform to existing topographical conditions. Any curve up to 10° will be no obstacle to a speed of 35 mi. per hr., the average speed of passenger trains. This practice will afford a range in

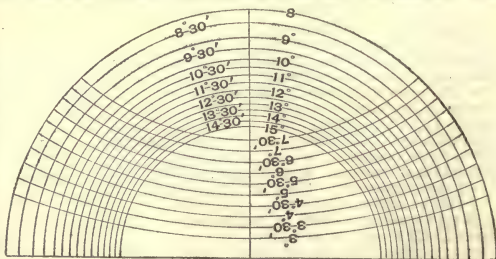


FIG. 2

curvature that will meet the requirements of almost any locality.

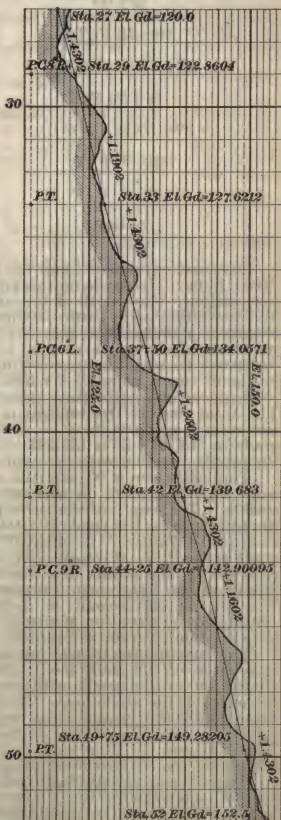
**Compensation for Curvature.**—The effect of curvature on a railroad line is to cause a resistance to the movement of trains. When a curve occurs on a

gradient, the effect of the curve resistance on ascending trains is practically the same as increasing the gradient. It is customary, when fixing the final grades, to lighten the grade on a curve by an amount sufficient to offset the resistance due to the curvature. This operation is called *compensating for curvature.* The usual rate of compensation for curvature is .03 to .05 ft. per 100 ft. per degree of curvature. For example, where the maximum gradient on tangents is 1%, the maximum gradient on a 6° curve, allowing a compensation of .03 ft. per degree, would be $1-(.03\times6)=.82\%$. If a compensation of .05 ft. per degree were made, the grade on a 6° curve would be $1-(.05\times6)=.70\%$.

**Final Grade Lines.**—The establishing of final grade lines is illustrated in Fig. 3, where the uncompensated grade is 1.3%, and the compensation for curvature, as shown on the final grade line, is .03 ft. per degree. The location notes for this line are as given on page 122.

The elevation of the grade at Sta. 27 is fixed at 120 ft., and at Sta. 52, at 152.5 ft., giving between these stations an actual rise of 32.5 ft. and an uncompensated grade of 1.3%. These grade points are marked on the profile with small circles. The total curvature between Sta. 27 and Sta. 52 is 108½°. The resistance due to each degree of curvature being taken as equivalent to an increase of .03 ft. in grade, the total resistance due to 108.5° is equivalent to $.03\times108.5=3.255$ ft. additional rise between Sta. 27 and Sta. 52. Hence, the total theoretical grade between these stations is the sum of 32.5 ft., the actual rise, and 3.255 ft. due to curvature, or 35.755 ft. Dividing 35.755 by 25, the number of stations in the given distance, there results $35.755\div25=+1.4302$ ft., as the grade for tangents on this line. The starting point of this grade is at Sta. 27. The P. C. of the first curve is at Sta. 29, giving a tangent of 200 ft. which is equal to two stations. As the grade for tangents is $+1.4302$ ft. per station, the rise in grade between Sta. 27 and Sta. 29 is $1.4302\times2=2.8604$ ft. The elevation of grade at Sta. 27 is 120 ft., and the elevation of grade at Sta. 29 is $120+2.8604=122.8604$ ft. which is recorded on the profile as shown in the diagram, with the rate of grade, namely, $+1.4302$, written above the grade line. The first curve is 8°, and, as the compensation per degree is .03 ft., then, for 8°, and a full station, the compensation is $.03\times8=.24$ ft. The grade on the curve will therefore be the tangent grade minus the compensation, or $1.4302-.24=+1.1902$ ft. per station. The P. C. of this curve is at Sta. 29, the P. T. at Sta. 33, making the total length of the curve 400 ft. or four stations. The grade on this curve is

FIG. 3

$+1.1902$ ft. per station and the total rise on the curve is $1.1902\times4=4.7608$ ft. The elevation of the grade at the P. C. at Sta. 29 is 122.8604; hence, the elevation of grade at the P. T. at Sta. 33 is $122.8604+4.7608=127.6212$ ft., which is recorded on the profile together with the grade, namely, $+1.4302$, written above the grade line. The P. C. of the next curve is at Sta. 37+50, giving an intermediate tangent of 450 ft., or four and one-half stations. The grade for tangents is $+1.4302$ ft. per station; hence, the total rise on the tangent is $1.4302\times4.5=6.4359$ ft. Adding 6.4359 ft., to 127.6212 ft., the elevation


of grade at Sta. 37+50 is found to be 134.0571 ft., which is recorded on the profile, together with the rate of grade for tangents.

## LOCATION NOTES

| Stations | Intersection Angles |
|---|---|

| 33+00 P. T. | |
| 29+00 P. C. 8° R. | 32° 00' |
| 27+00 | Beginning of grade |

The next curve is 6°, and the compensation in grade per station is .03 ft. ×6 = .18 ft. The grade on this curve will therefore be 1.4302 − .18 = 1.2502 ft. per station. The length of the curve is 450 ft., or four and one-half stations, and the total rise in grade on this curve is +1.2502 ft. ×4.5 = 5.6259 ft. The elevation of the grade at Sta. 37+50, the P. C. of the curve, is 134.0571. The elevation of the grade at Sta. 42, the P. T., is therefore 134.0571+5.6259 = 139.683 ft., which is recorded on the profile, together with the rate of grade on the 6° curve, namely, +1.2502. The P. C. of the next curve is at Sta. 44 +25, giving an intermediate tangent of 225 ft., or two and one-fourth stations. The total rise on the tangent is, therefore, 1.4302×2.25 = 3.21795 ft. The elevation of grade at the P. T. at Sta. 42 is 139.683; therefore, the elevation of grade at Sta. 44+25 is 139.683+3.21795 = 142.90095 ft., which is recorded on the profile, together with the grade +1.4302.

The last curve is 9°, and the compensation in grade per station is .03×9 = .27 ft. The grade on this curve is, therefore, 1.4302 − .27 = 1.1602 ft. per station. The length of the curve is 550 ft., or five and one-half stations, and the total rise on the curve is 1.1602×5.5 = 6.3811 ft. The elevation of grade at Sta. 44+25, the P. C. of the 9° curve, is 142.90095; hence, the elevation of grade at the P. T., at Sta. 49+75, is 142.90095+6.3811 = 149.28205 ft., which is recorded on the profile, together with the grade, +1.1602. The end of the line is at Sta. 52, giving a tangent of 225 ft., or two and one-fourth stations. The rise on this tangent is 1.4302×2.25 = 3.21795 ft., which is added to 149.28205, the elevation of the P. T. at Sta. 49+75. The sum, 152.5 ft., is the elevation of grade at Sta. 52.

The sum of the partial grades should equal the total rise between the extremities of the grade line. The points where the changes of grade occur are marked on the profile with small circles, which are connected by fine lines representing the grade line. These points of change are projected on a horizontal line at the bottom of the profile. The portions of this line that represent curves are dotted, and the portions that represent tangents are drawn full. The P. C. and P. T. of each curve are marked with small circles on this horizontal line, and are lettered as shown in the diagram.

Where the grades are light and the curves have large radii, there will be no need of compensation for curvature. Where the grades exceed .5% and the curves 5°, compensation should be made.

## VERTICAL CURVES

If the grade of the center line of track changes at any point, the two grade lines that intersect at this point form with each other an angle more or less abrupt. If this angle points upwards, it is called a *spur;* if it points downwards, it is called a *sag.* The angles *CVD* in Fig. 1 (*a*) and (*b*) are spurs; the angles *CVD* in Fig. 2 (*a*) and (*b*) are sags.

**Vertical Curve at a Spur.**—If *AV* and *BV*, Fig. 3, are two grade lines meeting at *V*, a vertical curve *CMD* must be introduced to join these lines.

Between $C$ and $D$, the actual grade is established along the vertical curve $CMD$, instead of along $CV$ and $VD$. The projections $RT$ and $TS$ of the distances $VC$ and $VD$ from the vertex to the points at which the vertical curve begins and

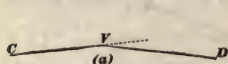

FIG. 1

FIG. 2

ends are always chosen equal. If $K$ is the middle point of the straight line $CD$, the vertical curve is always so chosen that it will bisect $VK$; that is, so that $VM = MK$.

Let $E$ be the elevation of $C$, Fig. 3, $E'$ that of $D$, and $H$ that of $V$, so that $E = RC$, $E' = SD$, and $H = VT$. Then,

$$VM = \tfrac{1}{2}\left(H - \frac{E + E'}{2}\right)$$

The distance $VM$ is called the *correction in grade* at the point $V$.

Vertical curves are always made parabolic. It is a property of the parabola that the correction in grade $am$ at any point $a$ is given by the equation,

$$am = VM\left(\frac{Ca}{CV}\right)^2$$

The distance $CV = VD$ is always made a whole number of stations; and, to simplify the work, the grade stakes $a$, $b$, $c$, etc., are so set that they divide the distance $CV$ into a number of equal parts. The corrections in grade at points $a'$, $b'$, and $c'$ along $DV$ are equal to those for the corresponding points along $CV$. That is, if $Ca = Da'$, then $am = a'm'$; if $Cb = Db'$, then $bm = b'm'$, etc.

EXAMPLE.—A

FIG. 3

$+.4\%$ grade meets a $-.5\%$ grade at Sta. 190, the elevation of which is 161.3 ft. If a vertical curve 400 ft. long is inserted, what is the correction in grade and the corrected grade elevation at each station and half station?

SOLUTION.—In this example, $VC = VD = 200$ ft. The elevation of $C$ is 161.3 $-2 \times .4 = 160.5$ ft., $= E$; that of $D$ is 161.3 $-2 \times .5 = 160.3$ ft., $= E'$; that of $K$ is $\tfrac{1}{2}(E' + E) = \tfrac{1}{2} \times (160.5 + 160.3) = 160.4$ ft.; and that of $V$ is $H = 161.3$ ft. Substituting these values in the formula for $VM$,

$$VM = \tfrac{1}{2} \times (161.3 - 160.4) = .45 \text{ ft.}$$

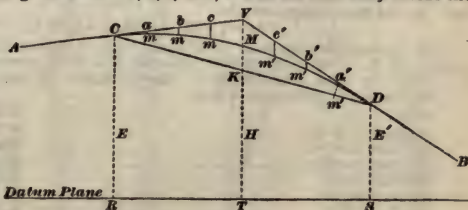
Since, for the first stake, $Ca = 50$ ft. and $CV = 200$ ft., the formula for $am$ gives

$$am = (\tfrac{50}{200})^2 \times VM = \tfrac{1}{16} \times .45 = .03 \text{ ft.} = a'm'$$

Similarly,

$$bm = (\tfrac{100}{200})^2 \times VM = \tfrac{1}{4} \times .45 = .11 = b'm'$$
$$cm = (\tfrac{150}{200})^2 \times VM = \tfrac{9}{16} \times .45 = .25 = c'm'$$

The original and corrected grade elevations are as follows:

| Station | Original Elevation | Correction | Corrected Elevation |
|---|---|---|---|
| 188 | 160.50 | .00 | 160.50 |
| +50 | 160.70 | .03 | 160.67 |
| 189 | 160.90 | .11 | 160.79 |
| +50 | 161.10 | .25 | 160.85 |
| 190 | 161.30 | .45 | 160.85 |
| +50 | 161.05 | .25 | 160.80 |
| 191 | 160.80 | .11 | 160.69 |
| +50 | 160.55 | .03 | 160.52 |
| 192 | 160.30 | .00 | 160.30 |


**Vertical Curve at a Sag.**—If two grade lines, $AV$ and $VB$, Fig. 4, meet so as to form a sag, the vertical curve will evidently be wholly above both grade lines. Using the same notation as before, the correction in grade at point $V$ will be

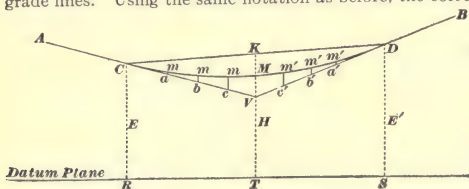


FIG. 4

$$VM = \tfrac{1}{2}\left(\frac{E+E'}{2}-H\right)$$

The correction in the grade at any point $a$ will be given by the preceding formula for $am$, as before. This correction, however, is now to be added to the old elevation of the grade at $a$ to obtain the corrected elevation.

EXAMPLE.—The grade of $CV$, Fig. 4, is $-1.2\%$, that of $VD$ is $+.6\%$, and the elevation of $V$ is $+49.2$ ft. Find the corrections in grade and the corrected elevations at stakes 100 ft. apart, if the length of the vertical curve is 600 ft.

SOLUTION.—The uncorrected grade elevations are as follows:

| *Along CV* | | *Along VD* | |
|---|---|---|---|
| At first stake............ | 52.8 | At fifth stake.......... | 49.8 |
| At second stake......... | 51.6 | At sixth stake......... | 50.4 |
| At third stake.......... | 50.4 | At seventh stake, $D$..... | 51.0 |
| At fourth stake, $V$ ......... | 49.2 | | |

Therefore,     $\tfrac{1}{2}(E+E') = \tfrac{1}{2}\times(52.8+51.0)=51.9$;

and, by the preceding formula,

$$VM = \tfrac{1}{2}\times(51.9-49.2)=1.35 \text{ ft.}$$

The formula for $am$ may now be applied. Correction in grade at second stake, 100 ft. from $C$, is $(\tfrac{100}{300})^2 \times 1.35 = \tfrac{1}{9}\times 1.35 = .15$, correction at sixth stake. Correction at third stake, $(\tfrac{200}{300})^2\times 1.35 = \tfrac{4}{9}\times 1.35 = .60$, correction at fifth stake.

The corrected elevations will be

| | | |
|---|---|---|
| At $C$.................................... | $52.80 + \ .00 =$ | $52.80$ |
| At second stake............................ | $51.60 + \ .15 =$ | $51.75$ |
| At third stake............................. | $50.40 + \ .60 =$ | $51.00$ |
| At fourth stake............................ | $49.20 + 1.35 =$ | $50.55$ |
| At fifth stake............................. | $49.80 + \ .60 =$ | $50.40$ |
| At sixth stake............................. | $50.40 + \ .15 =$ | $50.55$ |
| At $D$..................................... | $51.00 + \ .00 =$ | $51.00$ |

## CURVED TRACK

The difference in length between the inner and the outer rail of a standard-gauge curve may be found by either of the following rules:

**Rule I.**—*Multiply the degree of the curve by the length, in stations of 100 ft., and this product by $1\tfrac{1}{12}$; the result will be the difference in length between the inner and the outer rail, in inches.*

**Rule II.**—*Multiply the distance between the center lines of the rails by the length of the curve, in feet, and divide the product by the radius of the track curve; the quotient will be the required difference in length, expressed in feet.*

For light curves laid to exact gauge, the first rule is the simpler one, but for short curves where the gauge is widened, the second rule should be used.

**Curving Rails.**—When laying track on curves, in order to have a smooth line, the rails themselves must conform to the curve of the center line. To accomplish this, the rails must be curved. The curving should be done with a rail bender with a lever, preferably with the former. To guide those in charge of this work, a table of middle and quarter ordinates for a 30-ft. rail for all degrees of curve should be prepared. The middle ordinates in the following table are calculated by the formula

$$m = \frac{c^2}{8R},$$

in which $m =$ middle ordinate;

$c =$ length of chord, assumed to be of same length as rail;

$R =$ radius of curve.

This formula is not theoretically correct; yet the error is so small that it may be ignored in practical work.

In curving rails, the ordinate is measured by stretching a cord from end to end of the rail against the gauge side, as shown in the accompanying illustration. Suppose the rail $AB$ is 30 ft. in length, and the curve 8°, then the middle ordinate at $a$ should be

$$m = \frac{30^2}{8 \times 716.78} = .157 \text{ ft.} = 1\frac{7}{8} \text{ in.}$$
To insure a uniform curve to the rails, the ordinates at the quarter points $b$ and $b'$ should be tested. In all cases the quarter ordinates should be three-quarters of the middle ordinate. In the illustration, if the rail has been properly curved, the quarter ordinates at $b'$ and $b$ will be $\frac{3}{4} \times 1\frac{7}{8}$ in. $= 1\frac{13}{32}$, say $1\frac{3}{8}$.

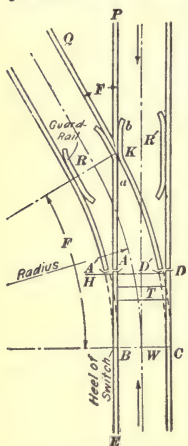
## MIDDLE ORDINATES FOR CURVING RAILS

| Degree of Curve | Length of Rail, in Feet | | | | | |
|---|---|---|---|---|---|---|
| | 30 | 28 | 26 | 24 | 22 | 20 |
| | Middle Ordinates, in Inches | | | | | |
| 1 | $\frac{1}{4}$ | $\frac{3}{16}$ | $\frac{3}{16}$ | $\frac{3}{16}$ | $\frac{1}{8}$ | $\frac{1}{8}$ |
| 2 | $\frac{7}{16}$ | $\frac{7}{16}$ | $\frac{3}{8}$ | $\frac{5}{16}$ | $\frac{1}{4}$ | $\frac{3}{16}$ |
| 3 | $\frac{11}{16}$ | $\frac{5}{8}$ | $\frac{9}{16}$ | $\frac{1}{2}$ | $\frac{7}{16}$ | $\frac{5}{16}$ |
| 4 | $\frac{15}{16}$ | $\frac{13}{16}$ | $\frac{11}{16}$ | $\frac{11}{16}$ | $\frac{9}{16}$ | $\frac{7}{16}$ |
| 5 | $1\frac{1}{16}$ | $1\frac{1}{16}$ | $\frac{7}{8}$ | $\frac{13}{16}$ | $\frac{11}{16}$ | $\frac{9}{16}$ |
| 6 | $1\frac{1}{16}$ | $1\frac{1}{4}$ | $1\frac{1}{16}$ | $\frac{15}{16}$ | $\frac{3}{4}$ | $\frac{5}{8}$ |
| 7 | $1\frac{3}{8}$ | $1\frac{1}{16}$ | $1\frac{1}{4}$ | $1\frac{1}{16}$ | $\frac{7}{8}$ | $\frac{11}{16}$ |
| 8 | $1\frac{7}{8}$ | $1\frac{5}{8}$ | $1\frac{5}{16}$ | $1\frac{3}{16}$ | $\frac{7}{8}$ | $\frac{3}{4}$ |
| 9 | $2\frac{1}{8}$ | $1\frac{7}{8}$ | $1\frac{5}{8}$ | $1\frac{1}{2}$ | $1$ | $\frac{15}{16}$ |
| 10 | $2\frac{3}{8}$ | $2\frac{1}{16}$ | $1\frac{3}{4}$ | $1\frac{1}{2}$ | $1\frac{1}{8}$ | $1\frac{1}{16}$ |
| 11 | $2\frac{5}{8}$ | $2\frac{1}{4}$ | $1\frac{15}{16}$ | $1\frac{11}{16}$ | $1\frac{3}{8}$ | $1\frac{1}{8}$ |
| 12 | $2\frac{13}{16}$ | $2\frac{5}{8}$ | $2\frac{1}{8}$ | $2\frac{1}{8}$ | $1\frac{9}{16}$ | $1\frac{1}{4}$ |
| 13 | $3\frac{1}{16}$ | $2\frac{11}{16}$ | $2\frac{5}{16}$ | $2\frac{5}{16}$ | $1\frac{5}{8}$ | $1\frac{3}{8}$ |
| 14 | $3\frac{5}{16}$ | $2\frac{7}{8}$ | $2\frac{1}{2}$ | $2\frac{1}{4}$ | $1\frac{3}{4}$ | $1\frac{1}{2}$ |
| 15 | $3\frac{3}{16}$ | $3\frac{3}{16}$ | $3\frac{1}{16}$ | $2\frac{11}{16}$ | $1\frac{11}{16}$ | $1\frac{9}{16}$ |
| 16 | $3\frac{1}{4}$ | $3\frac{1}{4}$ | $2\frac{13}{16}$ | $2\frac{5}{8}$ | $2\frac{5}{16}$ | $1\frac{11}{16}$ |
| 17 | $4$ | $3\frac{1}{2}$ | $3$ | $2\frac{9}{16}$ | $2\frac{1}{4}$ | $1\frac{3}{4}$ |
| 18 | $4\frac{1}{16}$ | $3\frac{11}{16}$ | $3\frac{3}{16}$ | $2\frac{11}{16}$ | $2\frac{5}{16}$ | $1\frac{7}{8}$ |
| 19 | $4\frac{5}{16}$ | $3\frac{7}{8}$ | $3\frac{3}{8}$ | $2\frac{5}{8}$ | $2\frac{1}{16}$ | $2$ |
| 20 | $4\frac{11}{16}$ | $4\frac{1}{2}$ | $3\frac{1}{16}$ | $3$ | $2\frac{3}{16}$ | $2\frac{1}{8}$ |

## TURNOUTS

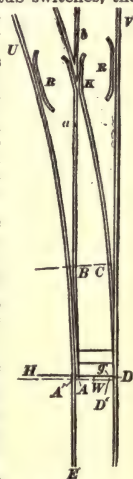
A *turnout* is a contrivance for passing from one track to another. The principal parts are the switch, the frog, and two guard-rails. The *switch*, which is the movable part of the turnout, consists of two switch rails $BA$ and $CD$, Fig. 1. The fixed ends $B$ and $C$ of the switch rails are called the *heels* of the switch, and the movable ends $A$ and $D$, the *toes* of the switch. The cross-tie that supports the toes of the switch is called the *head-block*, and the tie-rod at the toes, the *head-rod*. The distance $AA'$ or $DD'$ through which the toes move is called the *throw* of the switch. A frog is shown at $K$ and two guard-rails at $R$ and $R'$.

**Switches.**—There are two kinds of switches, which differ in the arrangement and form of switch rails, namely, the *stub switch* and the *point switch*. In the stub switch, Fig. 1, a part of each main-track rail is bent over to connect with the side track. In the point switch, Fig. 2, the outer rail $DV$ of the main track is spiked rigidly to the ties; the opposite rail $EA'U$, lying partly in the main track and partly in the side track, is also firmly spiked. These two rails are immovable. The two switch rails $BA$ and $CD$ are planed to thin edges at $A$ and $D$. The ends $B$ and $C$ of these rails are the fixed ends or heels; the thin edges at $A$ and $D$ are the toes. The head-block is at $H$, and the head-rod at $g$.

The point of the center line at which the turnout begins is called the *point of switch*. In Figs. 1 and 2, $W$ is the point of switch. In stub switches, the point of switch is midway between the heels; in point switches, it is midway between the toes and above the head-block.


**Frogs and Guard-Rails.**—A *frog* is a combination of rails so arranged that the broad tread of the wheel will always have a surface on which to roll, and that the flange of the wheel will have a channel through which to pass. A frog is shown in position on the track at $K$, Fig. 1, and a larger plan of the part at $ab$, Figs. 1 and 2, is shown in Fig. 3.

The wedge-shaped part $akb$ of the frog is called the *tongue* of the frog, and its point $k$ is called the *actual point of frog*. The actual point of frog is somewhat shortened and rounded. The intersection $c$ of the outside edges $ac$ and $bc$ of the tongue is called the *theoretical point of frog*. When the point of frog is referred to, the theoretical point is usually meant. The bent rails $wr$ are called *wing rails;* the narrowest part $mp$ of the frog is called the *throat*. The throat of the frog must be wide enough to allow the flanges of the wheels to pass through; it is usually made about 2 in. wide.

**Frog Angle and Frog Number.**—The angle $acb$, Fig. 3, between the outside edges of the tongue of the frog is called the *frog angle*. This is also equal to the angle $dce$ between the outside edges of the tongue produced beyond $c$. The frog angle which is represented by $F$ is also equal to the angle between the two tracks.


The distance $ab$ between the gauge lines at the end of the tongue is called the *heel width;* the distance $de$, the *mouth width*. If $sch$ is the bisector of the angle $F$, the distance $ch$ is called the *length of frog*.

The ratio of the length to the heel width is called the *frog number*, and is usually denoted by $n$; that is,

$$n = ch \div ab$$

The relation between $n$ and $F$ is expressed by the formulas

$$n = \tfrac{1}{2} \cot \tfrac{1}{2} F$$

and

$$\cot \tfrac{1}{2} F = 2n$$

FIG. 1

FIG. 2

FIG. 3

Frogs are usually designated by their numbers; thus, a No. 8 frog is one in which $n = 8$.

If the distance $sh$ and the widths $ab$ and $de$, Fig. 3, are measured on a frog, the frog number $n$ can be determined by the formula

$$n = \frac{sh}{ab + de}$$

**Guard-Rails.**—Guard-rails, which are usually from 10 to 15 ft. long, are placed opposite the frog on the main track and the switch track, as at $R$ and $R'$ in Figs. 1 and 2. The clear space between the head of the guard-rail and the head of the main or the switch rail should be about 2 in.

**Radius and Lead of a Turnout for Stub Switches.**—Let $RN$, Fig. 4, be the main track and $QP$ the turnout. Let $Q$ be the point of switch and $K$ the point of frog. If a stub switch is employed, the main-track rails will be securely spiked along $YB$ and $LD$; the parts $BG$ and $DV$ of these rails will be movable, so that they may be bent outwards to meet the turnout rails $W$ and $Z$. Here, then, the ends $B$ and $D$ are the heels of the switch, and $G$ and $V$ are the toes. The head-block is underneath $G$ and $V$.

In order to lay out a turnout when the frog angle is given, it is necessary to find the radius $r$, in terms of the frog angle, and the distance $KB$ from the point of frog to the heel of switch, which distance is called the *lead* and is designated by $L$.

FIG. 4

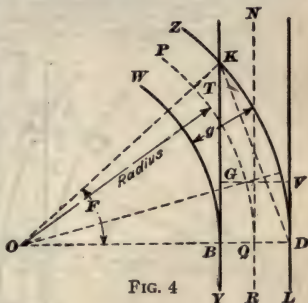
The formulas for $r$ and $L$ are:

$$r = \tfrac{1}{2}g \cot^2 \tfrac{1}{2}F = 2gn^2$$

and

$$L = g \cot \tfrac{1}{2}F = 2gn$$

In these formulas $g$ denotes the gauge. The *standard gauge* of track is 4 ft. $8\frac{1}{2}$ in. = 4.708 ft.

The accompanying table, some parts of which are calculated from the foregoing formulas, can be used in laying out a turnout with a stub switch. The


## DIMENSIONS OF STUB-SWITCH TURNOUTS

Track Circular From Heel of Switch to Point of Frog. Throw = 5½ In.

| Frog Number $n$ | Frog Angle $F$ | | | Lead $L$ | Chord $(QT)$ | Radius | Degree of Curve $d$ | Length of Switch Rails | Distance $Ka$, Fig.1 |

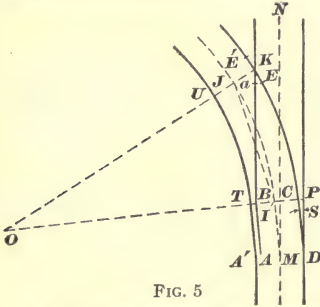
frog number, which is usually given, is stated in the first column; the corresponding frog angle in the second column; and the lead, or $BK$, Fig. 4, in the third column. Then follow columns containing the chord $QT$, Fig. 4, which is

equal to $2r \sin \frac{1}{2}F$; the radius of the turnout; the corresponding degree of curve
which is equal to $\dfrac{5{,}730}{r}$; the length $l$ of switch rails $AB$, Fig. 1, obtained by the

formula $l = \sqrt{t(2r - t)}$; and the distance $Ka$, Fig. 1, or $cw$, Fig. 3, With different forms of frogs, this distance varies; the engineer should therefore measure

FIG. 5

it for the different frogs he uses, as it is necessary in determining the length of spiked rail $Aa$, Fig. 1.


**Turnout Dimensions for Point Switches.**—Let $MN$, Fig. 5, be the center line of the main track and $MJ$ that of the turnout. Let $BA$ and $CD$ be the two switch rails whose fixed ends, or heels, are at $B$ and $C$, and whose toes are at $A$ and $D$. These rails are usually of a uniform length of 15 ft., except for the sharpest curves.

The center line $MIJ$ will, when a point switch is used, have a somewhat different position from that which it has when a stub switch is employed. In the stub-switch turnout, the rails $A'TU$ and $DCK$ are bent to a uniform curve between $M$

and $J$; in a point switch, the outer rail is made up of a straight part $DC$, which is the switch rail, and a curved part $CE$, which is tangent to $DC$ at $C$. On this account, the lead $A'K$ is less with a point switch than with a

## DIMENSIONS OF POINT-SWITCH TURNOUTS

Turnouts With Straight Point Rails and Straight Frog Rails;
Gauge 4 Ft. 8½ In.

| Frog Number $n$ | Frog Angle $F$ | | | Switch Angle $S$ (CDP) | | | Lead $L$ (A'K) | | | Radius $r$ | Degree of Curve $d$ | | | Chord (JI) | Length of Switch Rails (CD) | Length of Straight Frog Rail (KE) |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 4.0 | 14° | 15′ | 00″ | 3° | 40′ | | 32.20 | | | 125.21 | 47° | 05′ | | 23.09 | 7.5 | 1.50 |

stub switch. As point switches are used on the main line where very accurate work is required, it is necessary to take account of the fact that the short frog rails are not curved, the part $EE'$ of the rail being straight.

In computing the dimensions of a point-switch turnout, the usual data are the length $AB = DC$ of the switch rail, the angle $CDP$ between the outer switch rail and the main rail. This angle is called the *switch angle*, and will be represented by $S$. The frog number or the frog angle must also be known, as well

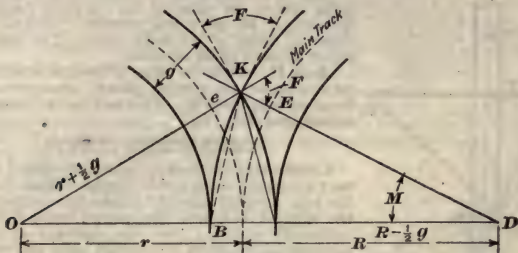

Fig. 6

as the length of the straight part $EE'$. It is then required to determine the radius $OI$ of the center line of a turnout whose outer rail shall be tangent to the switch rail $DC$ at $C$ and to the frog rail $EE'$ at $E$, and to find the lead $A'K$ of this turnout.

The formulas for computing these quantities are so complicated that, in practice, tables giving the various dimensions of point switches are always employed.

The accompanying table contains all the dimensions necessary for laying out a point switch when the frog number is known. It contains the frog angle, the switch angle $CDP$, Fig. 5, the lead $A'K$, the radius $OI$ of the center line of the turnout, the degree of curve of this center line, the chord $JI$, the length $AB = CD$ of the switch rails, and the length $KE = Ka$ of the straight frog rail.

**Turnouts From the Outer Side of a Curved Track.**—A turnout from the outer side of a curved track is shown in Fig. 6. The radius $DE = R$ of the main track, the frog angle $F$, or frog number $n$, and the gauge $g$ are usually known; from these the lead $BK = L$, and the radius $Oe = r$ of the center line of the turnout must be computed. The angle $M$, must first be found by the formula

$$\tan \tfrac{1}{2}M = \frac{g}{2R} \cot \tfrac{1}{2}F = \frac{gn}{R}$$

Then, the lead must be determined by the formula

$$L = 2(R + \tfrac{1}{2}g) \sin \tfrac{1}{2}M$$

Finally, $r$ is given by the formula

$$r + \tfrac{1}{2}g = \frac{R + \tfrac{1}{2}g}{\sin (F - M)} \sin M$$

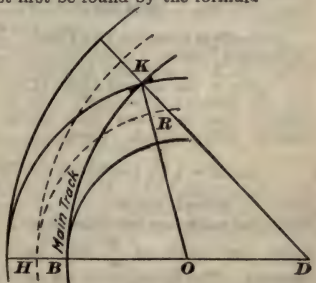
When $r$ has been found, the degree of curve is given by the formula

$$d = \frac{5,730}{r}$$

If the main-track curve is not very sharp, this value of $d$ may be obtained by subtracting the degree of curve of

Fig. 7

the main track from that obtained from the sixth column of the table for stub switches. The lead $L$ may also be taken from the table.

If the curvature of the main track is very sharp, or if the frog angle is very small, the turnout may curve in the same direction as the main track; in which case, the lead $L$ taken from the stub-switch table will be less than the degree of curve of the main track. The difference between the two degrees of curve will still be equal to the degree of curve of the turnout. If the degrees of curve are equal, the turnout rails will be straight.


**Turnout from the Inner Side of a Curved Track.**—A turnout from the inner side of a curved track is shown in Fig. 7. The radius $OR$ of the turnout is always less than the radius $DH$ of the main track. The degree of curve of the center line of the turnout and the lead $BK$ are found as follows:

**Rule I.**—*Take from the table for a stub or for a point switch, the value of the degree of curve corresponding to the given frog number. Add this to the degree of curve of the main track. The sum is the degree of curve of the turnout.*

**Rule II.**—*Take the value of the lead from the table for a stub or for a point switch, corresponding to the given frog number. This will be the value of the desired lead BK, Fig. 7.*

## CONNECTING CURVES

A *connecting curve* is a curve introduced to connect a turnout with a side track. Thus, in Fig. 8, the two parallel straight tracks are connected by the turnout $ME$ and the curved track $ED$. The values of $n$ and $g$, and the distance $a$, usually taken as 13 ft., must be known; then the radius $r' = O_1D = O_1E$, and distance $KT$ may be computed by the formulas

$$r' = 2(a-g) n^2 + \tfrac{1}{2}a$$

and

$$KT = \frac{a-g}{g} \times L$$

FIG. 8

$L$ is the lead $PK$ of the turnout, and, in such cases as this, is always to be taken from the table for a stub switch, even when the point switch is inserted, because in deriving the formula for $KT$, $QK$ and $ME$ are assumed to be circular arcs.

## CROSS-OVERS

A *cross-over* is a stretch of track that connects two parallel tracks, and enables a train to pass from one track to the other. Thus, in Fig. 9, if $UV$ and $U'V'$ are two parallel tracks, the track $RZR'$ is a cross-over. This cross-over consists of two equal turnouts $Rm$ and $R'm'$, whose frog angles at $K$ and $K'$ are equal, and a reversed curve $mZm'$ connecting the ends of these turnouts, $Z$ being the point of reversal.

**Cross-Over Between Two Parallel Straight Tracks.**—To lay out the cross-over, it is necessary to know the radius $r$, the central angle $M$, and the distance $BE = B'E'$. The radius $r$ may be taken from the table for stub switches. Then,

$$\sin M = \sqrt{\frac{a}{r}\left(1 - \frac{a}{4r}\right)}$$

and

$$BE = 2r \sin M$$

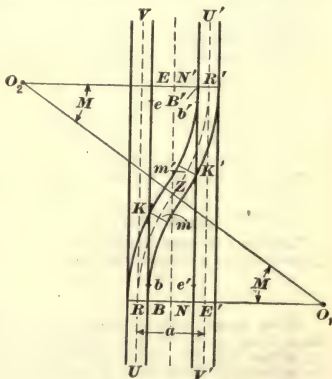
When the tracks are less than 30 ft. apart, the value of $\frac{a}{4r}$ may be dropped. The formulas for $\sin M$ and $BE$ then become, respectively,

$$\sin M = \sqrt{\frac{a}{r}}$$

and

$$BE = 2\sqrt{ar}$$

FIG. 9

The preceding formulas apply only to stub switches; to apply them to point switches, proceed as follows: Having located one frog point $K$ of the point-switch turnout, measure back from $K$ the lead $KB$ for a stub-switch turnout taken from the table, and from the point $R$ of the center line opposite $B$ run


in the curve $RmZ$ to the point of reversal. Then measure off the distance $BE = 2\sqrt{ar}$, and from the point $B'$ opposite to $E$ lay off the stub-switch lead $B'K'$ to locate the second point of frog $K'$. Then run in the center-line curve $R'Z$. The two frog points and the reversed curve $mZm'$ are thus located. Finally, measure back from $K$ and $K'$ the distances $Kb = K'b'$ equal to the lead for point switches, to locate the toes of the point switches at $b$ and $b'$, and complete the location of these switches as explained under Laying Out Turnouts.

It is evident that the whole length of the cross-over when point switches are employed is $be = b'e' = BE - 2 \times Bb = 2\sqrt{ar} - 2 \times Bb$. Therefore,

$$be = b'e' = 2\sqrt{ar} - 2 \times \text{(lead of stub switch} - \text{lead of point switch)}$$

A stake is usually driven at $Z$, midway between the inner rails and midway between the points $N$ and $N'$, and the turnout curves are continued to this point. This is more accurate than to attempt to determine the point of reversal by the use of the central angle $M$.

**Another Form of Cross-Over Between Two Parallel Straight Tracks.**—A second form of cross-over is shown in Fig. 10. In this form, the ends of the two equal turnouts are connected by a straight track $KTK'T'$. The cross-over with a reversed curve, Fig. 9, is much shorter than this straight-track cross-over, and thus requires less length of track and occupies less room. The straight-track form is, however, to be preferred; it is less wearing on the rolling stock because it gives the wheel trucks a better opportunity to adjust themselves to the reversion of curvature.

In order to lay out a straight-track cross-over, it is only necessary to compute the distance $BE = B'E'$, Fig. 10, in addition to the usual dimensions of the two turnouts, which may be done by taking the lead $L$ from the stubswitch table and applying the formula:

FIG. 10

$$BE = 2L - \frac{a}{4n} + (a - 2g)n$$

The turnout $Rm$ having been put in place, the distance $BE$ is laid off and the heels $B'$ and $H'$ of the second turnout are located opposite the point $E$. This turnout is then laid out as far as $m'$, and finally the straight rails $KT'$ and $K'T$ are laid adjoining the ends of the two turnouts.

The only modification of the work for a point switch arises from the fact that the lead $Kb = K'b'$ of the point switch is less than that of the stub switch. The whole length of cross-over is, for a point switch,

$$be = 2L' - \frac{a}{4n} + (a - 2g)n$$

Here $L'$ is the lead taken from the table for point switches.

## LAYING OUT TURNOUTS

**To Lay Out a Stub Switch.**—Having decided on the position of the end $b$, Fig. 11, of the frog rail, measure the total length of the frog and deduct from the length of the rail to be cut, marking with red chalk on the flange of the rail the point at which the rail is to be cut. From Fig. 3,

$$n = \frac{ch}{ab}$$

and
$$ch = n \times ab$$

To calculate the distance from the heel to the theoretical point of frog, the width of the frog at the heel is measured and multiplied by the frog number. For example, if the width of the frog at the heel is $8\frac{1}{2}$ in., and a No. 8 frog is to be used, the theoretical distance from the heel to the point of frog is $8.5 \times 8 = 68$ in. $= 5$ ft. 8 in. Measure off this distance from the point marking the heel of the frog; this will locate the point of frog, which should be distinctly marked with red chalk on the flange of the rail. It is a common practice to make a distinct mark on the web of the main-track rail, directly opposite to the point

of frog. This point, being under the head of the rail, is protected from wear and the weather. The heel of the turnout is then located by measuring back the lead from the point of frog. Next, make a chalk-mark on both main-track rails on a line marking the center of the head-block; a more permanent mark is made with a center punch. Stretch a cord touching these marks, and drive a stake on each side of the track, with a tack in each; this line should be at right angles to the center line of the track, and the stakes should be sufficiently far from the tracks not to be disturbed when putting in switch ties. Next, cut the switch ties to proper length; draw the spikes from the track ties, three or four at a time, and remove the ties from the track, replacing them with switch ties, and tamping the latter securely in place. When all the long ties are tamped, cut the main-track rail for the frog, being careful that the amount cut off is just equal to the length of the frog. If, by increasing or decreasing the length of the lead 5%, the cutting of a rail can be avoided, this should be done, especially for frogs above No. 8.

Full-length rails (30 ft.) should be used for moving or switch rails, and care should be taken to leave a joint of proper width at the head chair. The head-chairs should be spiked to the head-block so that the main-track rails will be in perfect line. From 8 to 10 ft. of the switch rails should be spiked to the ties. The tie-rods are placed between the switch ties, which should not be more than 15 in. from center to center of tie. The connection-rod should be attached to the head-rod and switch stand. With these connections made the switch stand is easily placed to give the proper throw of the switch.

It is common practice to fasten the switch stand to the head-block with track spikes, but a better fastening is made with bolts. The stand is first properly placed, the holes are marked and bored, and the bolts passed through from the under side of the head-block. This obviates all danger of movement of the switch stand in fastening, which is liable to occur when spikes are used, and insures a perfect throw.

The use of track spikes is admissible when holes are bored to receive them, in which case a $\frac{3}{8}$-in. auger should be used for standard track spikes. The switch stand should, when possible, be placed facing the switch, so as to be seen from the engineer's side of the engine — the right-hand side.

FIG. 11

FIG. 12

To find the position of the chord of the arc of the outer rail of the turnout curve, stretch a cord from the heel $a$, Fig. 11, to the point $b$, of the frog. Mark the middle point $c$ and the quarter points $d$ and $e$, and at these points lay off the offsets $dd'$, $cc'$, and $ee'$. Add to these offsets the distance from the gauge line to the outside of the rail flange, and mark the points on the switch ties. Spike the rail to these marks and place the other at easy track gauge from it. Spike the rails of the turnout, as far as the point of frog, to exact gauge, unless the gauge has been widened owing to the sharpness of the curve. Beyond the point of frog, the curve may be allowed to vary a little in gauge to prevent a kink from showing opposite the frog. In case the gauge is widened at the frog, increase the guard-rail distance an equal amount. For a gauge 4 ft. 8$\frac{1}{2}$ in., place the side of the guard-rail that comes in contact with the car wheels at 4 ft. 6$\frac{5}{8}$ in. from the gauge line of the frog. This gives a space of 1$\frac{7}{8}$ in. between the main rail and the guard-rail. In case the gauge is widened $\frac{1}{4}$ or $\frac{1}{2}$ in., increase the guard-rail distance an equal amount.

When the turnout curve is very sharp, it will be necessary to curve the switch rails, to avoid an angle at the head-block. The rails should be carefully curved before being laid, and great pains should be taken to secure a perfect line.

**To Lay Out a Point Switch.**—The frog point $K$, Fig. 12, having been located exactly as for a stub switch, the lead $KB$ is next laid off from $K$ to the toe of switch $B$, and the positions of $B$ and $D$ are marked on the main-track rails. From $D$, the length $DN$ of the switch rail, which is usually 15 ft., is then

measured forwards to $N$, and the position of $N$ is marked on the web or flange of the rail. The heel $M$ is usually $5\frac{3}{4}$ in. from the point $N$. The point $I$ is located on a line perpendicular to $MD$ and at a distance $\frac{1}{2}g$ from $M$. The point $J$ is similarly located from the point $H$. As a check on the work, the length of the chord $JI$ should have the value given in the table for point switches.

Switch ties of the requisite number and length should be prepared and placed in the track in proper order. As in the case of stub switches, all long switch ties should be in place before the rail is cut for placing the frog; also, the ends $M$ and $L$ of the rails, with which the switch points connect, should be exactly even; otherwise the tie-rods will be skewed, and the switch will not work or fit well. The tie-rods should next be fastened in position, care being taken to place them in their proper order, the head-rod being numbered 1. Each rod is marked with a center punch, the number of punch marks corresponding to the number of the rod.

The switch rails are now coupled with the rails $LK$ and $MK$, and the sliding plates are then placed in position and securely spiked to the ties. The head-rod is then connected with the switch stand, and the switch is closed, giving a clear main track. The stand is then adjusted for this position of the switch, and bolted fast to the head-block. Next, rail $BR$ is crowded against the switch point so as to insure a close fit, and secured in place with a rail brace at each tie. The laying of the rails of the turnout is then continued.

The rail $MH$ is to be bent and spiked in place by laying off offsets from the chord $MH$ exactly as explained for stub switches. The rail between $M$ and $H$ usually consists of two pieces of plain rail bent to the proper curve. The outer rail of the main track is not disturbed.

**Switch Timbers.**—Every first-class railroad has its own standards for switches, which include the necessary switch timbers. The number of ties and their lengths may be determined by the following rules:

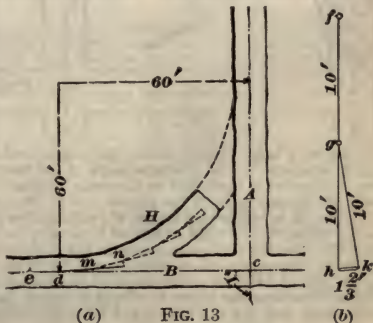
**Rule I.**—*To find the number of ties required for any switch lead, reduce to inches the distance from the head-block to the last long tie behind the frog, and divide this distance by the number of inches from center to center of ties; the quotient will be the number of ties required.*

$(a)$     FIG. 13     $(b)$

**Rule II.**—*Measure the length of the tie next the head-block and the length of the last long tie behind the frog. Find the difference, in inches, between them. Divide this difference by the number of ties in the switch lead; the quotient will be the increase in length per tie from the head-block toward the frog to have the ends of the tie in proper line on both sides of the track.*

**Practical Method of Laying Out Sharp Curves in a Mine.**—Curves in a mine are usually so sharp that they are designated as curves of so many feet radius, instead of as curves of so many degrees. For example, suppose that it is required to connect the two headings $A$ and $B$, Fig. 13 $(a)$, which are perpendicular to each other, with a curve of 60 ft. radius. Prepare the device shown in $(b)$, by taking three small wires or inelastic strings $fg$, $gh$, and $gk$, each 10 ft. long, and connecting one end of each to a small ring, and the other end of two to the ends of a piece of wood $1\frac{2}{3}$ ft. long. Form a neat loop at end $f$ of string $gf$.

To use this device, lay off on the center line of the heading $B$, $cd$ and $de$ equal to 60 ft. and 10 ft., respectively. Place the loop $f$ of the device described over a small wire peg driven in at $e$, and the ring $g$ over a similar peg at $d$. Take hold of the stick $hk$, pull the strings $gh$ and $gk$ taut, and place the center mark on $hk$ on the center line of the heading $B$. Drive a small peg in at $m$, located by the point $k$, which is on the curve. Move the device forwards, place the loop $f$ over the peg at $d$, the ring $g$ over the peg at $m$, and take hold of the stick $hk$ and pull until the strings $gh$ and $gk$ are taut, and the strings $fg$ and $gh$ are in a straight line. The point $k$ will fall on the curve at $n$, which mark by driving in a peg. To locate other points, proceed exactly as in the last step. The distance $cd$ in any case is found by the formula

$$cd = R \tan \tfrac{1}{2}I,$$


in which        $R$ = radius of curve;
                $I$ = intersection angle of center lines of headings.

Fig. 14 shows a graphic method of laying out curves, when it is desired to connect a main entry $a$ with a cross-entry $b$ by a curve of a given radius. Here, $c$ is the point of curve on the main-entry center line and $d$ is the point of tangency on the center line of the cross-entry, which is assumed to be turned off at right angles from the main entry. From $c$ and $d$, arcs with a radius equal to

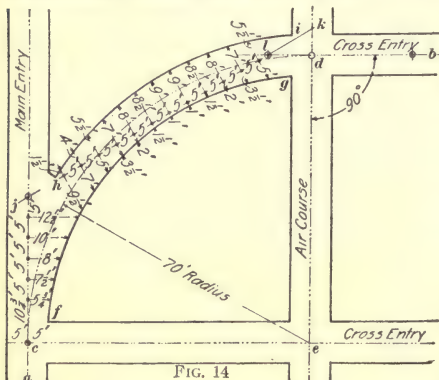


FIG. 14

the desired radius of c u r v a t u r e are described, thus locating the center $e$ of the c u r v e. From this point, with the same radius, the curve $cd$, which is the center of the proposed passageway, is described. The curves $fg$ and $hi$ are then drawn, making the curved entry any desired width. Line $jk$, so l o c a t e d that it will not cut either rib of the curved roadway, should then be drawn and on it points 5 feet apart should be laid off to the given scale and the right and left distances to the rib scaled, as shown in the figure. If a plat of this kind is

drawn on a large enough scale, the angles and distances may be scaled sufficiently accurate for the practical work of the mine foreman. A blueprint or tracing of the plat is furnished to the mine foreman, and from it he lays off the right and left distances from the center line of the main entry and from the line $jk$. The line $jk$ is located by means of two stations placed with the transit at $b$ and a point either to the right or left of $b$, as may be most convenient, and along the line $bl$. For the distances given in the illustration and the radius of curvature of 70 ft., the angle $cjk$ as taken from the drawing is about 120° 15'; the angle at $jld$, about 149° 45'; the distance $cj$, 35 ft. 9 in.; $jl$, 58 ft.; and $ld$, 11 ft. 6 in. These distances are given as about so much, to show that they are scaled from a drawing and are not calculated by trigonometry.

---

# STADIA SURVEYING

*Stadia surveying* is the process of measuring distances and elevations by observing through a telescope the distance intercepted on a rod between two horizontal cross-hairs. These hairs are carried on the same ring as the regular horizontal cross-hair, and are equidistant from it. The rod used may be an ordinary level rod, but, if much stadia work is to be done, it is advisable to select some one of the special rods designed for the work; a description of these may be found in any instrument maker's catalog.

The distance intercepted on the rod between the cross-hairs of the telescope bears a certain relation to the distance of the rod from the instrument. As the transit is provided with a vertical circle or arc, the angle of inclination between the line of sight and the horizon may be determined in case of inclined sights. The space intercepted between the cross-hairs on the rod, taken in connection with the vertical angle, enable the distance and elevation of the rod to be calculated. When the line of sight is horizontal, the distance $d$ of the rod from the instrument can be determined from the formula

$$d = sR + i,$$

in which    $R$ = stadia reading or distance intercepted between the stadia wires;
            $s$ = stadia constant;
            $i$ = instrument constant.

The values of the stadia and instrument constants are usually determined by the instrument maker. The *instrument constant* varies from about .75 ft. to 1.33 ft. in different transits, according to the size and power of their telescopes. Its value is usually marked on a card attached to the inside of the instrument box. It is a general rule that unless definitely stated to the contrary, the *stadia constant* is made equal to 100; that is, in a horizontal line of sight, the stadia wires will intercept a distance of 1 ft. on a rod whose distance from the instrument is 100 ft. plus the instrument constant. Thus, if the stadia constant is 100 and the instrument constant is 1.33 ft., if the stadia wires intercept a distance of 8.37 ft. on the rod, the distance from the rod to the transit is $8.37 \times 100 + 1.33 = 838.33$ ft.; the line of sight being horizontal.

Stadia wires are either fixed or adjustable. The former are firmly placed by the instrument maker so that the stadia constant is 100. They cannot get out of adjustment and are much to be preferred to the other and older method of mounting, in which the distance between the wires may be varied to intercept any distance on the rod. In the event of the constants not being known, they may be determined as follows: Select a piece of level ground and set tacks in stakes at exactly 50 ft. apart for a distance of 400 to 800 ft. Let $R_2$ and $R_1$ be two stadia readings taken at the respective distances $d_2$ and $d_1$; then,

$$s = \frac{d_2 - d_1}{R_2 - R_1}$$

and

$$i = \frac{d_1 R_2 - d_2 R_1}{R_2 - R_1}$$

Several pairs of readings and their corresponding distances are substituted in these formulas, and the mean of all the resulting values of $s$ and $i$ calculated.

EXAMPLE.—Determine the stadia and the instrument constant from the following data:

| Distance Measured Feet | Rod Reading Feet |
|---|---|
| 50 | .488 |
| 100 | .988 |
| 200 | 1.988 |
| 300 | 2.991 |
| 400 | 3.986 |

SOLUTION.—Take 50 ft. for the value of $d_1$ and 100 ft., 200 ft., etc. successively for the values of $d_2$, and apply the preceding formulas for $s$ and $i$. For the first pair of observations:

$$s = \frac{100 - 50}{.988 - .488} = 100$$

and

$$i = \frac{50 \times .988 - .488 \times 100}{.988 - .488} = 1.200 \text{ ft.}$$

The other values are figured in a similar manner and the whole is tabulated as follows:

| $s$ | $i$ |
|---|---|
| 100.000 | 1.200 |
| 100.000 | 1.200 |
| 99.880 | 1.258 |
| 100.057 | 1.172 |
| 4)399.937 | 4)4.830 |

means      $99.984 = s$      $1.208 = i$

**Reduction of Inclined Sights.**—For the purpose of determining distances and differences in elevation when the rod is above or below the level of the instrument what are known as stadia reduction tables have been prepared. Their use is best explained by an illustration.

EXAMPLE.—Using a transit with fixed cross-hairs, the stadia constant being 100 and the instrumental constant being 1, the distance intercepted on the rod was 4.25 ft. and the vertical angle was $18° 23'$. What was the horizontal and the vertical distance from the rod to the instrument?

SOLUTION.—Referring to the table in the column headed $18°$ and opposite $22'$ in the column headed M, for $18° 22'$ a horizontal distance of 90.07 is found; and opposite $24'$, for $18° 24'$, a horizontal distance of 90.04 is found. For $18° 23'$, therefore, the horizontal distance will be the mean, or 90.055. The first column of the three lowest lines of the table contains the symbols $c = .75$,

$c = 1.00$, and $c = 1.25$. In this $c$ is the instrument constant, the value of which is given by the maker. In the case in question $c = 1.00$. Following horizontally along the line of $c = 1.00$, the figures .95 are found in the column headed "18° Hor. Dist." This .95 is the proportion of the instrument constant to be added to the reduced distance when the vertical angle is between 18° and 19°. The horizontal distance is then,

$$\text{Distance} = \text{rod reading} \times \text{tabular horizontal distance} + c;$$

From this

$$\text{distance} = 4.25 \times 90.055 + .95 = 382.73 + .95 = 383.68 \text{ ft.}$$

Referring again to the table but using the second of the two columns under 18°, that headed Diff. Elev. and by interpolating between the values of 22' and 24', the Diff. Elev. for 18° 23' is found to be 29.925. The proportion of the instrumental constant is found, in the line beginning $c = 1.00$ in the column headed 18° but under the subcolumn, Diff. Elev., to be .32 for all values of the vertical angle between 18° and 19°. The difference in elevation is then

$$\text{Diff. Elev.} = \text{rod reading} \times \text{tabular Diff. Elev.} + c$$

From this

$$\text{Diff. Elev.} = 4.25 \times 29.925 + .32 = 127.18 + .32 = 127.50 \text{ ft.}$$

**Use of Stadia.**—The stadia is not used as much as it should be by the mining engineer, particularly in securing data for making a contour map of the property of which he is in charge. In rolling and hilly country, some points upon the surface may be from 500 to 1,500 ft. higher than others and this difference in the thickness of the rocks, and consequent pressure upon the coal, will have a great bearing on the thickness of pillars, method of drawing stumps, etc., underground. If the traverse made to determine the boundaries of the property has been made with a 400-ft. tape, the elevations of the stations are known from the distances and vertical angles. By setting up at the various stations, stadia sights may be taken to points at any distances within which the rod may be read. This will be 1,200 or 1,400 ft. for a 12-ft. or 14-ft. rod. Sights of double this distance may be taken if the upper hair and the regular horizontal hair are used instead of the two stadia hairs; that is, if the two upper hairs are used in place of the first and third. Distances so determined must be multiplied by 2, as they are half distances. In this case the engineer must be certain that the horizontal hair is exactly midway between the stadia hairs. This may be ascertained by reading a distance with the upper and middle hairs and then with the middle and lower hairs. If these distances are the same, the hairs are evenly spaced; if the distances do not agree, their mean must be taken.

Cloudy days when the air is free from vibrations are best for stadia work. An ordinary erecting transit will give excellent results up to 1,200 and 1,800 ft., depending on its power, and a high class inverting telescope with large objective may be used for distances up to 3,000 ft. A good rodman is essential, and if long sights are being taken and the slopes are regular, one observer can keep two rodmen busy. The rod should be held at all points where there is any marked change in the degree of slope. Small inequalities in the surface may be neglected, it being apparent that an error of 20 to 30 ft. in determining the thickness of the rocks overlying the seam is of no importance.

When the sights are too long to permit of the rod being plainly read, the rodman should drive a stake and place a tack in it to mark the station. The edge of the rod should then be held on the tack, the rodman running his hand up and down the side of the rod that is to be sighted to. The transitman should then move up and take further stadia sights from the station just established. In traversing valleys or swales cutting across a property or in determining the line of a ridge all the work may be done with the stadia with a degree of accuracy well within reasonable requirements and far more easily, rapidly, and cheaply, than with a transit, 400 ft. tape, and leveling instrument. In locating isolated and distant houses, the opposite side of a wide river from that on which the traverse is being run, in fact in all work where an error of 1 : 500 or 1 : 1,000 is allowable, the stadia is to be preferred to the tape.

Stadia Reduction Table

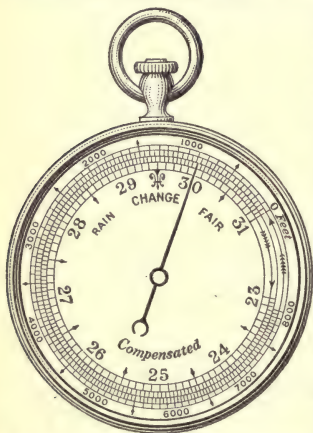
## BAROMETRIC LEVELING

Of the two types of barometer in general use, the *mercurial barometer* is better adapted for work at permanent stations, and the *aneroid barometer*, shown in the accompanying figure, by reason of its portability, is better suited for use in the field. In the barometer, the difference in the pressure of the air at two different stations not in the same horizontal plane, is made the basis for measuring the difference in their elevation. The aneroid barometer consists of a circular metallic air-tight box, either of brass or aluminum (because of its lightness). One side is covered with a thin corrugated plate and only enough air is left within the box to compensate for the diminished stiffness of the cover at higher temperatures. This cover rises or falls as the outer pressure changes, and this motion is greatly magnified by a series of levers and is transmitted to a pointer moving over a scale on the circumference of the outer face. This scale is commonly doubly graduated. The inner scale is graduated by inches, tenths, and hundredths, to correspond with the graduations of a standard mercurial barometer. The outer scale is graduated in thousands, hundreds, and tens of feet, indicating elevations above sea level corresponding to the atmospheric pressures recorded by the inner scale. The



fineness of these outer graduations varies, the ordinary aneroid reading direct to 10 ft. and by estimation to, say, 2 ft., while very large forms of the instrument are provided with a vernier, magnifying glass, etc., by which they may be read to single feet. Such refinement in reading is unnecessary, as instrument and weather irregularities introduce much greater uncertainties than those caused by too coarse graduating.

In some aneroids the two sets of graduations are fixed, the zero of the altitude scale being opposite the 31-in. mark of the mercurial scale, and this relation cannot be changed, but in most instruments of this kind the zero may be shifted either by turning an arrangement like the stem of a watch or by turning the milled edge of the aneroid itself. The zero of the altitude scale may be made to coincide with either the 30- or 31-in. mark of the mercurial scale, but whichever mark is decided on by the instrument maker must always be used. That this is the case will be obvious from the table of Barometric

Elevations, which shows that a difference of 1 in. in the length of the mercurial column between 29 and 30 inches corresponds to a difference of 924 ft. in elevation, whereas a difference of 1 in. of mercury between 13 and 14 in. corresponds to a difference of 2,020 ft. in elevation. Hence, as the length of the altitude scale corresponding to a difference in elevation of 1,000 ft. is not uniform, any shifting of the zeros of the two scales will bring inharmonious graduations opposite one another.

Aneroids vary in size from $1\frac{3}{4}$ to $2\frac{1}{2}$ to 3 in. in diameter for the standard forms up to 5 in. in diameter for the larger ones provided with a vernier, etc. They are commonly graduated from 31 in. down to 27, 25, 21, 19, 17, and 14 in. of mercury, corresponding to approximate elevations of from 1,000 ft. below sea level to 3,000, 5,000, 10,000, 12,000, 16,000, and 20,000 ft. above sea level. The larger barometers are no more accurate than the smaller ones and nothing is gained by having them graduated to record smaller pressures (greater elevations) than those prevailing where the instrument is to be used. Thus, east of the Mississippi River, a 2-in. or $2\frac{1}{2}$-in. aneroid graduated from 27 to 32 in. (corresponding to elevations of 3,000 ft. above to 2,000 ft. below sea level), will answer for all purposes of the coal-mining engineer, except for exploratory work in the highest mountains of the Carolinas, etc. A barometer reading to 17 in. (about 16,000 ft.) will answer for all parts of the continental

United States, as the highest peaks of the Rocky Mountains are but little over 14,000 ft. high. It must be remembered that the less the pressure (the greater the altitude) the barometer will record, the finer are the graduations on both scales and, consequently, the more difficult is precise reading.

A small screw in the center of the back permits the index pointer to be accurately adjusted to correspond with the reading of a standard mercurial barometer. This adjustment is originally made by the instrument maker, but the aneroid should be compared from time to time with a standard barometer at some station of the United States Weather Bureau, or elsewhere.

The word *compensated* stamped on the face of an aneroid barometer does not mean that in determining elevations differences in temperature are not to be considered, but only that the instrument reads correctly at all temperatures and that no allowance need be made for the effect of changes in temperature upon the instrument itself.

Too much reliance must not be placed on the accuracy of elevations as determined by the aneroid. All this instrument does is to measure the pressure of the air at a given place at a certain time. As this pressure must and does vary at the same place as the weather changes, it must be apparent that the difference in elevation between two distant points can be determined with even approximate accuracy only when two barometers are used and which are read simultaneously at the two points in question. At sea level, 1 in. of the mercurial column corresponds to a difference in elevation of about 900 ft. Changes of $\frac{1}{10}$ in. frequently take place in 1 hr., $\frac{2}{10}$ in. in 1 da., and in event of storms, ranges of 1 in. are not unusual. Thus, as $\frac{1}{10}$ in. represents about 90 ft. of elevation, a single reading of the barometer may give an elevation for a place 900 ft. greater or less than the true one under unfavorable atmospheric conditions, and one of as much as 100 ft. under the best. On the other hand, if the barometer is read two or three times daily for a period of 1 yr. or more, the temperature being noted at the same time and the proper corrections made, a very fair idea may be obtained as to the difference in elevation between the station in question and that of any other station at which simultaneous observations have been made. Thus, the daily readings may be made by the engineer at some isolated station and their mean for a period of time compared with those made at any station of the United States Weather Bureau any number of miles distant.

**Barometric Formulas.**[*]—The general formula for obtaining the difference of elevation between two points is,

$$z = 60,520[1 + .001017(t + T - 64)] \log \frac{H}{h}$$

in which $z$ = difference of elevation of the two points;

$h$ and $t$ = reading of barometer and thermometer at upper station;
$H$ and $T$ = reading of barometer and thermometer at lower station.

This equation may be referred to an approximate sea level (height of mercurial column 30 in. instead of 29.92 in.) and to a mean station temperature of 50° F., that is $t + T$ is made equal to 100° F., in which $t$ and $T$ may have any values as long as their sum equals 100° F. Making the substitutions

$$z = 62,737 \log \frac{30}{h} - 62,737 \log \frac{30}{H}$$

The accompanying table of Barometric Elevations, from the United States Coast and Geodetic Survey, contains values for $62,737 \log \frac{30}{h}$ for all readings of the aneroid from 13 to 31 in. for use in connection with the foregoing formula, no allowance being made for the amount of aqueous vapor in the air. At other temperatures and for an assumed average humidity a correction obtained from the table of Corrections for Temperature and Humidity must be applied to the difference in elevation as obtained from the first table. Thus, if $A$ is the difference in elevation obtained from the table of Barometric Elevations, and $C$ the correction for temperature and humidity from the second table,

$$z = A (1 + C)$$

**EXAMPLE.**—The means of the readings of the barometer and the thermometer at the summit and base of a mountain were: Summit, barometer 17.92 in., thermometer 26° F.; base, barometer 24.15, thermometer 64° F. If the

elevation of the base was 6,025 ft. above sea level, what was the elevation of the summit?

SOLUTION.—From the first table,

$$\text{Height for 17.92 in.} = 14,039.6 \text{ ft.}$$
$$\text{Height for 24.15 in.} = 5,910.5 \text{ ft.}$$

$$\text{Approx. difference in elevation} = 8,129.1 \text{ ft.}$$

As $T+t=90°$, from the second table, $C=-.0058$, and

$$z = 8,129.1 \times (1-.0058) = 8,082 \text{ ft.}$$
$$\text{Elevation of base} = 6,025 \text{ ft.}$$

$$\text{Elevation, top of mountain} = 14,010 \text{ ft.}$$

**Use of Barometer.**—The mining engineer ordinarily has but one aneroid and this is not commonly provided with a thermometer. With a single instrument reliable results are difficult to obtain, and depend as much on good and uniform weather conditions as on the skill and carefulness of the engineer. In fact, the results obtained during storms, whether of wind or rain, are not to be relied on at all. The single aneroid, then, should be used only when weather conditions are of the best. In the morning, before starting out, its reading should be noted and recorded. If a thermometer is available, it, too, should be read. As the aneroid is usually employed in exploratory work in which more or less time is required to examine various coal openings, it should be read a few minutes after reaching an opening and again on leaving, the times and temperatures being noted as well. After the examination of one opening is completed, the engineer should hasten as rapidly as possible to the next; that is, he should move rapidly from place to place but should remain a sufficient time at each to estimate the changes in pressure (and consequently in apparent elevation) that are taking place. By taking two observations at each opening at intervals of, say, ½ hr., a correction curve showing the changes in pressure may be worked out by means of which an allowance may be made for these changes while the barometer is being carried from place to place. Thus, a reading at Sta. A at 9.15 A. M., showed an elevation of 810 ft., and a reading at Sta. B at 9.30 A. M. showed one of 860 ft., and a second at B at 10 A. M. indicated 875 ft. This last reading shows a change in apparent elevation of 15 ft. in 30 min., or at the rate of .5 ft. per min. The apparent difference in elevation between A and B (first readings) is 50 ft., but a part of this difference is due to a change in the atmospheric pressure. The two readings at Sta. B show that the elevations are apparently increasing at the rate of .5 ft. per min.; therefore, as it took 15 min. to go from A to B, the elevation of B over A apparently increased 7.5 ft. Hence, the actual difference in elevation between A and B is not 50 ft. but $50-7.5=42.5$ ft. Very satisfactory results may be obtained in this way; and if the time between stations is short, corrections for changes in temperature, etc., need not be made, provided the difference in

elevation is not great. By taking double readings at each station, a continuous curve can be worked out and applied to correcting the day's observations. If possible, the aneroid should be reread at the various openings on the way home, and the mean of the afternoon and morning readings taken as the true reading. The instrument should be read upon reaching the starting point at night and again when leaving the next morning.

When two barometers are available, their readings are compared at starting, one being carried into the field and the other retained at headquarters where it is read by an assistant throughout the day at intervals of 10 or 15 min., a record being kept of the time, temperature, and pressure. The field man, then, need take but one reading at a station, preferably just before leaving, and should likewise note the temperature and time. These double readings, unless the field-man is so far from the base that weather conditions are markedly different, afford a complete check on fluctuations in pressure due to changed atmospheric conditions.

**Care of the Barometer.**—The aneroid should not be removed from its case; should not be subjected to violent jars; nor exposed to or read while affected by artificial heat. It should be read in a horizontal position, and on sunny days should be allowed to remain in the shade for, say, 5 min. before being read, that all its parts may have time to assume the temperature of the air at the station.

## PRACTICAL PROBLEMS IN SURVEYING

**1. To Prolong a Straight Line.**—Let $AB$, Fig. 1, be a straight line whose position on the ground is fixed by stakes set at $A$ and $B$, and let it be required to prolong the line to $C$. This can be done in two ways; namely, by foresight only, or by backsight and foresight, the

Fig. 1

latter method being commonly called backsight.

*By Foresight.*—The transit is set over the point at $A$, and the line of sight directed to a flag held at $B$; if the point $C$ is to be set at a given distance from $B$, the chainmen measure the required distance, the head chainman being kept in line by the transitman. When the required distance has been measured, the point $C$, which evidently lies in the prolongation of $AB$, is marked by a stake or otherwise.

*By Backsight.*—The transit is set over the point at $B$ and a sight taken on a flag held at $A$. The telescope is then plunged so that it is directed along the prolongation of $AB$. Any required distance $BC$ may then be measured from $B$ in the direction indicated by the line of sight.

**2. To Run a Line Over a Hill When the Ends of the Line Are Invisible From Each Other.**—The points $A$ and $B$, Fig. 2, are supposed to be on the opposite sides of a hill, and to be invisible from each other. It is desired to run a line between them, or to locate some intermediate points.

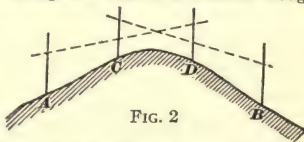

Fig. 2

Having set two poles at $A$ and $B$, two flagmen with poles station themselves at $C$ and $D$, approximately in line with $A$ and $B$, and in such positions that the poles at $B$ and $D$ are visible from $C$, and those at $C$ and $A$ are visible from $D$. The flagman at $C$ lines in the pole at $D$ between $C$ and $B$, and then the flagman at $D$ lines in that at $C$ between $D$ and $A$. Then the flagman at $C$ again lines in that at $D$, and so on, until $C$ is in the line between $D$ and $A$ at the same time that $D$ is in line between $C$ and $B$. The points $C$ and $D$ will then be in line with $A$ and $B$.

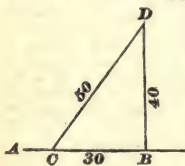

Fig. 3

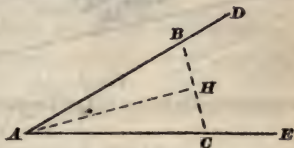
**3. To Erect a Perpendicular to a Line at a Given Point.**—Let it be required to erect a perpendicular to the line $AB$ at the point $B$, Fig. 3. A triangle whose sides are in the proportion of 3, 4, and 5 is a right triangle, the longest side being the hypotenuse; for $5^2 = 4^2 + 3^2$. The following method is based on this principle: Lay off on $BA$ a distance $BC$ of 30 ft. (or li.). Fix one end of the chain at one of the extremities as $C$, and the end of the nineties link at the other extremity $B$. Hold the end of the fiftieth link

and draw the chain until both parts are taut. The point $D$ where the end of the fiftieth link is held will then be a point in the perpendicular, and the direction of the latter will therefore be $BD$.

The distance $BC$ may be any other convenient multiple of 3. In general, if $BC$ is denoted by $3a$, $BD$ must be $4a$, and $CD$ must be $5a$. Thus, $BC$ may be made equal to 21 $(=3\times7)$ li.; in which case $BD$ must be $4\times7=28$, and $CD$ must be $5\times7=35$ li. As $35+28=63$, one end of the chain must be fixed at one of the extremities of $BC$, the end of the sixty-third link at the other extremity, and the chain pulled from the end of the thirty-fifth link until both parts are taut.

FIG. 4

**4. To Determine the Angle Between Two Lines.**—Let $AD$ and $AE$, Fig. 4, be two lines on the ground. To determine the angle $DAE$, measure off from $A$ on $AD$ and $AE$ equal distances $AB$ and $AC$. Measure the distance $BC$. Then the angle $DAE$ is calculated from the relation


$$\sin \tfrac{1}{2}DAE = \frac{\tfrac{1}{2}BC}{AB}$$

EXAMPLE.—If $AB$ and $AC$ are each 100 ft. and $BC$ is 57.6 ft., what is the value of the angle $DAE$?

SOLUTION.—Substituting the values of $BC$ and $AB$ in the formula,

$$\sin \tfrac{1}{2}DAE = \frac{\tfrac{1}{2}\times57.6}{100} = .28800;$$

whence, $\tfrac{1}{2}DAE = 16°\ 44'$, nearly; and, therefore, $DAE = 16°\ 44' \times 2 = 33°\ 28'$.

**5. To Find the Distance of an Inaccessible Point.**—*Case I.*—Let it be required to determine the distance from the point $B$ to an inaccessible point $P$,

FIG. 5

Fig. 5. Measure $BC$ in any convenient direction and run a line $A'D'$ parallel to $BC$. Measure $AD$, the distance between the points where the lines $PB$ and $PC$ intersect $A'D'$. Measure also $AB$. Then,

$$BP = \frac{AB \times BC}{AD - BC}$$

EXAMPLE.—If, in Fig. 5, $BC = 100$ ft., $AB = 52.4$ ft., and $AD = 124.2$ ft., what is the distance $BP$?

SOLUTION.—Substituting these values in the formula,

$$BP = \frac{52.4 \times 100}{124.2 - 100} = 216.5 \text{ ft.}$$

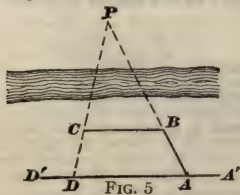
*Case II.*—Measure a horizontal base line $AB$, Fig. 6, and take the angles formed by the lines $BAC$ and $ABC$, which gives two angles and the included side. Assuming the angle $A$ to be $60°$; the angle $B$ $50°$; and the side $AB = 500$ ft., angle $C = 180° - (60° + 50°) = 70°$.

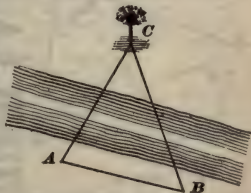
Then, $\sin 70° : AB = \sin A : BC$, and $\sin 70° : AB = \sin B : AC$; or, $.939693 : 500 = .866025 : BC$, or $460.8+$, and $.939693 : 500 = .766044 : AC$, or $407.6+$.

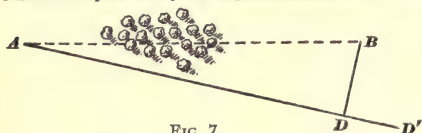
By logarithms:

FIG. 6

$$\begin{array}{ll}
\text{Log } 500 = & 2.698970 \\
\text{Log sin } 60° = & 9.937531 \\
\hline
& 12.636501 \\
\text{Log sin } 70° = & 9.972986 \\
\hline
& 2.663515 = \text{log of } 460.8+.
\end{array}$$

$$\begin{array}{ll}
\text{Log } 500 = & 2.698970 \\
\text{Log sin } 50° = & 9.884254 \\
\hline
& 12.583224 \\
\text{Log sin } 70° = & 9.972986 \\
\hline
& 2.610238 = \text{log of } 407.6+.
\end{array}$$




**6. To Determine the Distance Between Two Points Invisible From Each Other or Separated by an Impassable Barrier.**—*Case I.*—Let it be required to find the distance between two points $A$ and $B$, Fig. 7, that are invisible from each other. First run a random line $AD'$ in such a manner that it will pass as near $B$ as can be estimated. From $B$ drop a perpendicular $BD$ on $AD'$ and compute the required distance $AB$ by the formula


$$AB = \sqrt{AD^2 + BD^2}$$

EXAMPLE.—If, in Fig. 7, the distance $AD$ is 206.1 ft. and the distance $BD$ is 35.1 ft., what is the distance from $A$ to $B$?

SOLUTION.—Here $AD = 206.1$ and $BD = 35.1$; therefore, substituting in the formula, $AB = \sqrt{206.1^2 + 35.1^2} = 209.1$ ft.

*Case II.*—Select any convenient station, as $C$, Fig. 8, measure the lines $CA$ and $CB$, and the angle included between these sides, so as to obtain two sides and the included angle. Assuming the angle $C$ to be 60°, the side $CA$, 600 ft., and the side $CB$, 500 ft., the following formula is obtained:

$$CA + CB : CA - CB = \tan \frac{A+B}{2} : \tan \frac{B-A}{2}.$$

Then, $\dfrac{A+B}{2} = \dfrac{180° - 60°}{2}$, or 60°.

Then, $1,100 : 100 = \tan 60° : \tan \dfrac{B-A}{2}$; or, $1,100 : 100 = 1.732050 : .157459$,

or tangent of $\dfrac{B-A}{2}$, or 8° 57'.

Then, $\qquad 60° + 8° 57' = 68° 57'$, or angle $B$,
and $\qquad 60° - 8° 57' = 51° 03'$, or angle $A$,

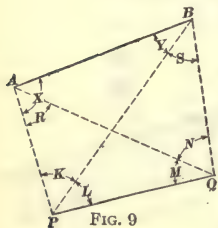
Having found the angles, find the third side by the same method as case II, of problem 5.

The foregoing formula, worked out by logarithms, is as follows:

$$\begin{aligned}
\text{Log } 100 &= 2.000000 \\
\text{Log tan } 60° &= 10.238561 \\
&\overline{\phantom{0}12.238561} \\
\text{Log } 1,100 &= 3.041393 \\
&\overline{\phantom{0}9.197168} = \text{log tan of } \frac{B-A}{2}, \text{ or 8° 57'.}
\end{aligned}$$

Then,
$\qquad 60° + 8° 57' = 68° 57'$, or angle $B$,
and $\qquad 60° - 8° 57' = 51° 03'$, or angle $A$

NOTE.—The greater angle is always opposite the greater side.

**7. To Find the Distance Between Two Inaccessible Objects When Points Can Be Found From Which Both Objects May Be Seen.**—Let $AB$, Fig. 9, be the line, the ends $A$ and $B$ of which are inaccessible. Select two points $P$ and $Q$ from which both ends of the line can be seen, and at a distance from each other of about 300 or 400 ft. Measure the line $PQ$, and the angles $K$, $L$, $M$, and $N$.


Then, from triangle $APQ$,

$$AP = \frac{PQ \sin M}{\sin R}$$

in which $R = 180° - (K+L) - M$.
From triangle $BPQ$,

$$BP = \frac{PQ \sin (M+N)}{\sin S}$$

in which $S = 180° - L - (M+N)$.

FIG. 7

FIG. 8

FIG. 9

Then, from triangle $ABP$,

$$\tan \tfrac{1}{2}(X-Y) = \frac{BP-AP}{BP+AP} \cot \tfrac{1}{2}K$$

and

$$AB = \frac{(BP-AP)\cos \tfrac{1}{2}K}{\sin \tfrac{1}{2}(X-Y)}$$

EXAMPLE.—If, in Fig. 9, the distance $PQ$ is 400 ft., and the angles, as measured, are $K = 37°\ 10'$, $L = 36°\ 30'$, $M = 52°\ 15'$, $N = 32°\ 55'$, what is the distance $AB$?

SOLUTION.—In the triangle $APQ$, $R = 180° - (37°\ 10' + 36°\ 30' + 52°\ 15')$ $= 54°\ 05'$, and

$$AP = \frac{400 \sin 52°\ 15'}{\sin 54°\ 05'} = 390.53 \text{ ft.}$$

In the triangle $BPQ$, $S = 180° - (36°\ 30' + 52°\ 15' + 32°\ 55') = 58°\ 20'$, $M+N = 52°\ 15' + 32°\ 55' = 85°\ 10'$, and

$$BP = \frac{400 \sin 85°\ 10'}{\sin 58°\ 20'} = 468.30 \text{ ft.}$$

Also, $K = 37°\ 10'$, $\tfrac{1}{2}K = 18°\ 35'$, and

$$\tan \tfrac{1}{2}(X-Y) = \frac{(468.30-390.53)}{468.30+390.53} \cot 18°\ 35'$$

whence, $\tfrac{1}{2}(X-Y) = 15°\ 04'$, and therefore

$$AB = \frac{(468.30-390.53)\cos 18°\ 35'}{\sin 15°\ 04'} = 283.58 \text{ ft.}$$

**8. To Determine the Angle Between Two Lines AB and CD, Whose Point of Intersection P is Inaccessible, Also, the Distances BP and DP.**—This problem is of frequent occurrence in railroad work, the two given lines being the center lines of two straight tracks that are to be connected by a curve Measure the distance $BD$, Fig. 10, and the angles $K$ and $L$. Then, $M = 180° - (K+L)$, $I = K+L$, $BP = \dfrac{BD \sin L}{\sin M}$, and $DP = \dfrac{BD \sin K}{\sin M}$.

FIG. 10

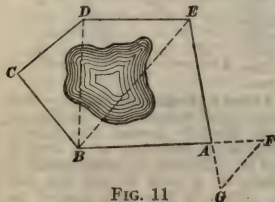
**9. Survey of a Closed Field.**—If a closed field is to be surveyed without the aid of an angle-measuring instrument, the area may be divided into triangles by means of diagonals, which are measured on the ground. The area of each triangle may then be determined by the formula $A = \sqrt{s(s-a)(s-b)(s-c)}$ in which $a$, $b$, and $c$ represent the three sides and $s$ represents one-half of their sum, or $\dfrac{a+b+c}{2}$.


FIG. 11

When obstacles make it impossible to measure directly the diagonals of a field, as, for instance, the diagonal $BE$, Fig. 11, a tie line $FG$ parallel to $BE$ is run and measured. Then,

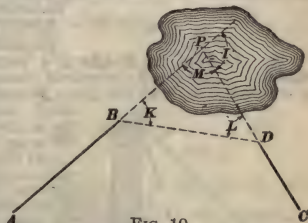
$$BE = \frac{GF \times AB}{AF}$$

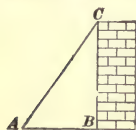
To run the line $FG$, produce $BA$ and select any convenient point $F$ and measure $AF$. Then produce $EA$ and locate $G$ from the relation

$$AG = \frac{AF \times AE}{AB}$$

EXAMPLE.—In Fig. 11, let the lengths of the sides be as follows: $AB = 320$ ft., $BC = 217$ ft., $CD = 196$ ft., $DE = 285$ ft., and $EA = 304$ ft. It is required to calculate the length of the diagonal $BE$ by means of a tie-line.

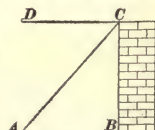
SOLUTION.—Let the line $BA$ be prolonged 100 ft. beyond $A$; that is, make $AF = 100$ ft. Then $AG$ must be equal to $\dfrac{AF \times AE}{AB} = \dfrac{100 \times 304}{320} = 95$ ft. Let the length of $GF$, as found by measurement, be 125 ft. Then,

$$BE = \frac{GF \times AB}{AF} = \frac{125 \times 320}{100} = 400 \text{ ft}$$


**10. To Determine the Height of a Vertical Object Standing on a Horizontal Plane.**—Measure from the foot of the object any convenient horizontal distance $AB$, Fig. 12; at the point $A$, take the angle of elevation $BAC$. Then, as $B$ is known to be a right angle, two angles and the included side of a triangle are obtained. Assuming that the line $AB$ is 300 ft. and the angle $BAC = 40°$, the angle $C = 180° - (90° + 40°) = 50°$. Then, sin $C : AB = $ sin $A : BC$, or $.766044 : 300 = .642788 : BC$, or $BC = 251.73+$ ft. Or, by logarithms:


$$\text{Log } 300 = 2.477121$$
$$\text{Log sin } 40° = 9.808067$$
$$\overline{12.285188}$$
$$\text{Log sin } 50° = 9.884254$$
$$\overline{2.400934 \text{ or log of } 251.73+ \text{ ft.}}$$

**11. To Find the Distance of a Vertical Object Whose Height is Known.** At a point $A$, Fig. 13, take the angle of elevation to the top of the object. Knowing that the angle $B$ is a right angle, the angles $B$ and $A$ and the side $BC$ are known. Assuming that the side $BC = 200$ ft. and the angle $A = 30°$, a triangle is formed as follows: Angle $A = 30°$, $B = 90°$, $C = 60°$, and the side $BC = 200$ ft. Then sin $A : BC = $ sin $C : AB$, or $.5 : 200 = .866025 : AB$, or $AB = 346.41$ ft. By logarithms:

$$\text{Log } 200 = 2.301030$$
$$\text{Log sin } 60° = 9.937531$$
$$\overline{12.238561}$$
$$\text{Log sin } 30° = 9.698970$$
$$\overline{2.539591 \text{ or log of } 346.41 \text{ ft.}}$$


**12. To Find the Height of a Vertical Object Standing Upon an Inclined Plane.**—Measure any convenient distance $DC$, Fig. 14, on a line from the foot of the object, and, at the point $D$, measure the angles of elevation $EDA$ and $EDB$, and the angle $CDB$; also at $C$ measure the angle $BCD$. In the triangle $BDC$, the side $BD$ may be calculated for the angles at $D$ and $C$ and the side $CD$ are known. Then, in the right-angled triangle $BED$ the sides $BE$ and $ED$ may be calculated, as the side $BD$ and the angle at $D$ are known. Next, in the right-angled triangle $AED$, the side $AE$ may be calculated, for the side $ED$ and the angle at $D$ are known. Finally, the height of the object may be found by subtracting the length $AE$ from the length $BE$.

**13. To Find the Height of an Inaccessible Object Above a Horizontal Plane.**—*First Method.*—Measure any convenient horizontal line $AB$, Fig. 15, directly toward the object, and take the angles of elevation at $A$ and $B$. In the triangle $ABC$, the side $AC$ may be calculated as the angles at $A$ and $B$ and the side $AB$ are known. Then, in the right-angled triangle $CDA$, the side $CD$, which is the height of the object, may be calculated as the angle at $A$ and the side $AC$ are known.

*Second Method.*—If it is not convenient to measure a horizontal base line toward the object, measure any line $AB$, Fig. 16, and also measure the horizontal angles $BAD$, $ABD$, and the angle of elevation $DBC$. Then, by means of the two triangles $ABD$ and $CBD$, the height $CD$ can be found. Then, with the line $AB$ and the angles $BAD$ and $ABD$ known, the third angle is readily found, and the side $BD$ can be found. Then, in the triangle $BDC$, the angle $B$ is known, by measurement, $D = 90°$, and the side $BD$ is known. Then, the side $CD$, or the vertical height, can be found by preceding methods.

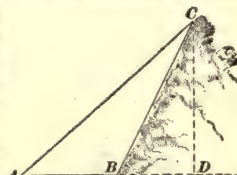
Fig. 16


# MECHANICS

## ELEMENTS OF MECHANICS

### GENERAL LAW

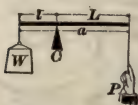
All machinery, however complicated, is merely a combination of six elementary forms, viz.: the *lever*, the *wheel and axle*, the *pulley*, the *inclined plane* the *wedge*, and the *screw*; and these six can be still further reduced to the lever and the inclined plane. They are termed *mechanical powers*, but they do not produce force; they are only methods of applying and directing it. The law of all mechanics is:

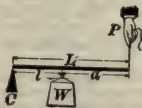
Law.—*The power multiplied by the distance through which it moves is equal to the weight multiplied by the distance through which it moves.*

Thus, 20 lb. of power moving through 5 ft. = 100 lb. of weight moving through 1 ft. In the following discussion friction is not considered.

### LEVERS

There are three classes of levers: (1) power at one end, weight at the other, and fulcrum between, as shown in Fig. 1; (2) power at one end, fulcrum at





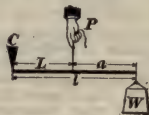


FIG. 1         FIG. 2         FIG. 3

the other, and weight between, as shown in Fig. 2; (3) weight at one end, fulcrum at the other, and power between, as shown in Fig. 3.

The handle of a blacksmith's bellows is a lever of the first class; the hand is the power and the bellows the weight, with the pivot between as the fulcrum. A crowbar used for prying down top rock is a lever of the second class; the hand is the power, the rock to be barred down the weight, and the point in the roof against which the bar presses is the fulcrum. The treadle of a grindstone is a lever of the third class; the foot is the power, the hinge at the back of the foot is the fulcrum, and the moving of the machinery is the weight. A lever is in equilibrium when the arms balance each other. The distances through which the power and the weight move depend on the comparative length of the arms.

Let

$P$ = power;
$W$ = weight;
$L$ = power's distance from fulcrum $C$;
$l$ = weight's distance from fulcrum $C$;
$a$ = distance between power and weight;

Arranging these terms according to the law of mechanics,

$$PL = Wl, \text{ or } P : W = l : L$$

$$P = \frac{Wl}{L} \qquad W = \frac{PL}{l}$$

In levers of the first class, $a = L + l$;

whence $\qquad L = \dfrac{Wa}{W+P} \qquad\qquad l = \dfrac{Pa}{W+P}$

In levers of the second class, $a = L - l$;

whence $\qquad L = \dfrac{Wa}{W-P} \qquad\qquad l = \dfrac{Pa}{W-P}$

In levers of the third class, $a = l - L$;

whence $\qquad L = \dfrac{Wa}{P-W} \qquad\qquad l = \dfrac{Pa}{P-W}$

In first- and second-class levers, as ordinarily used, power is gained and time is lost; in the third class, power is lost and time is gained.

EXAMPLE.—Having a weight of 2,000 lb. to lift with a lever, the short end of which is 2 ft. from the fulcrum and the long end 10 ft., how much power will be required?

SOLUTION.—Applying the formula $L : l = W : P$, $10 : 2 = 2,000 : P$; whence $P = (2,000 \times 2) \div 10 = 400$ lb.

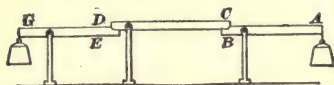
The *compound lever*, Fig. 4, consists of several levers so constructed that the short arm of the first acts on the long arm of the second, and so on to the last. If the distance from $A$ to the fulcrum is four times the distance from the


FIG. 4

fulcrum to $B$, then a power of 5 lb. at $A$ will lift 20 lb. at $B$. If the arms of the second lever are of the same comparative length, the 20-lb. power obtained at $B$ will exert a pressure of 80 lb. on $E$; and if the third lever has the same comparative lengths, this 80 lb. at $E$ will lift 320 lb. at $G$. Thus, a power of 5 lb. at $A$ will balance a weight of 320 lb. at $G$. But, in order to raise the weight 1 ft., the power must pass through $320 \div 5 = 64$ ft.

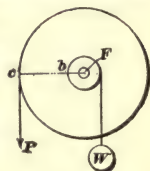
## WHEEL AND AXLE

The *wheel and axle*, Fig. 5, is a modification of the lever. The ordinary windlass is a common form. The power is applied to the handle, the bucket is the weight, and the axis of the windlass is the fulcrum. The long arm of the lever is the handle, and the short arm is the radius of the axle. Thus, $F$ is the fulcrum, $Fc$ the long arm, and $Fb$ the short arm. The wheel and axle has the advantage that it is a kind of perpetual lever. It is not necessary to prop up the weight and readjust the lever, but both arms work continuously.

FIG. 5

By turning the handle or wheel around once, the rope will be wound once around the axle, and the weight will be lifted that distance. Applying the law of mechanics, power × circumference of wheel = weight × circumference of axle; or, as the circumferences of circles are proportional to their radii, $P : W = r : R$; whence $PR = Wr$. Therefore,

$$P = \frac{Wr}{R} \qquad R = \frac{Wr}{P}$$

$$W = \frac{RP}{r} \qquad r = \frac{RP}{W}$$


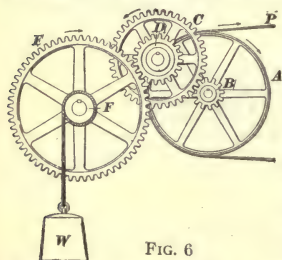
A *train*, Fig. 6, consists of a series of wheels and axles that act on one another on the principle of a compound lever. The *driver* is the wheel to which power is applied. The *driven wheel* or *follower*, is the one that receives motion from the *driver*. The *pinion* is the small gear-wheel on the axle.


FIG. 6

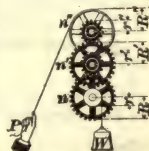
If the diameter of the wheel $A$ is 16 in., and of the pinion $B$ 4 in., a pull of 1 lb. applied at $P$ will exert a force of 4 lb. on the wheel $C$; if the diameter of $C$ is 6 in., and of $D$ 3 in., a force of 4 lb. on $C$ will exert a force of 8 lb. on $E$. If $E$ is 16 in. in diameter, and $F$ 4 in., a force of 8 lb. on $E$ will raise a weight of 32 lb. on $F$. In order, however, to lift this amount, according to the principle already named, the weight will only pass through one thirty-second of the distance of


FIG. 7

the power. Thus, power is gained and speed lost. To reverse this, power may be applied to the axle, and, with a correspondingly heavy power, speed gained. Referring to Fig. 7, applying the law of mechanics,

$$P = \frac{Wrr'r''}{RR'R''} \qquad W = \frac{PRR'R''}{rr'r''}$$

$$n : n'' = r'r'' : RR'$$
$$v : v' = rr'r'' : RR'R''$$

in which      $n, n', n''$ = number of revolutions;
     $v, v'$ = velocity or speed of rotation;
     $r, r', r''$, etc. = radii of pinions;
     $R, R', R''$, etc. = radii of wheels.

## INCLINED PLANE

In Fig. 8, the power must descend a distance equal to $AC$ in order to elevate the weight to the height $BC$; hence, $P \times$ length of inclined plane $= W \times$ height of inclined plane, or $P : W =$ height of inclined plane : length of inclined plane; or,

$$P = \frac{Wh}{l} \qquad W = \frac{Pl}{h} = \frac{P}{\sin a}$$

FIG. 8

**To Find Weight Required to Balance Any Weight on Any Inclined Plane.**—Multiply the given weight by the sine of the angle of inclination. Thus, to find the weight required to balance loaded car weighing 2,000 lb. on a plane pitching 18°, multiply 2,000 by the sine of 18°, or $2,000 \times .309017 = 618.034$ lb.

Or, if the length of the plane and the vertical height are given, multiply the load by the quotient of the vertical height divided by the length. Thus, if a plane between two levels is 300 ft. long and rises 92.7 ft., and the load is 2,000 lb., the balancing weight is found as follows: $2,000 \times \frac{92.7}{300} = 618$ lb.

*Case I.*—To find the horsepower required to hoist a given load up an inclined plane in a given time, use the formula

$$\frac{\text{(Load, in lb.} + \text{weight of hoisting rope, in lb.)} \times \text{vertical height load is raised, in ft.}}{33,000 \times \text{time of hoisting, in minutes}}$$

EXAMPLE.—Find the horsepower required to raise, in 3 min., a car weighing 1 T. and containing 1 T. of material up an inclined plane 1,000 ft. long and pitching 30°, if the rope weighs 1,500 lb.

SOLUTION.—The total load equals car + contents + rope = 2,000 + 2,000 + 1,500 = 5,500 lb. The vertical height through which the load is hoisted equals $1,000 \times \sin 30° = 1,000 \times .5 = 500$ ft.; therefore, H. P. = $\frac{5,500 \times 500}{33,000 \times 3} = 27.7$.

*Case II.*—When the power acts parallel to the base, use the formula
$$W \times \text{height of inclined plane} = P \times \text{length of base.}$$

These rules are theoretically correct, but in practice an allowance of about 30% must be made for friction and contingencies.

## SCREW

The *screw* consists of an inclined plane wound around a cylinder. The inclined plane forms the thread, and the cylinder, the body. It works in a nut that is fitted with reverse threads to move on the thread of the screw. The nut may run on the screw, or the screw in the nut. The power may be applied to either, as desired, by means of a wrench or a lever.

When the power is applied at the end of a lever, it describes a circle of which the lever is the radius $r$. The distance through which the power passes is the circumference of the circle; and the height to which the weight is lifted at each revolution of the screw is the distance between two of the threads, called the *pitch*, $p$. Therefore, $P \times$ circumference of circle $= W \times$ pitch; or $P : W = p : 2\pi r$; whence,

$$P = \frac{Wp}{2\pi r} \qquad W = \frac{2\pi r P}{p}$$

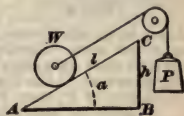
The power of the screw may be increased by lengthening the lever or by diminishing the distance between the threads.

EXAMPLE.—How great a weight can be raised by a force of 40 lb. applied at the end of a wrench 14 in. long, using a screw with 5 threads per in.?

SOLUTION.—Substituting in the formula $W \times \frac{1}{5} = 40 \times 28 \times 3.1416$; whence $W = 17,593$ lb.

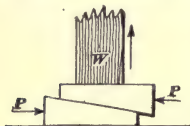
## WEDGE

The *wedge* usually consists of two inclined planes placed back to back, as shown in Fig. 9. In theory, the same formula applies to the wedge as to the inclined plane, Case II.

$$P : W = \text{thickness of wedge : length of wedge.}$$


Friction, in the other mechanical powers, materially diminishes their efficiency; in this it is essential, since, without it, after each blow the wedge would fly back and the whole effect be lost. Again, in the others the power is applied as a steady force; in this it is a sudden blow, and is equal to the momentum of the hammer.

FIG. 9

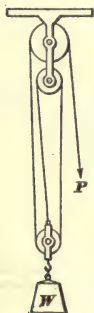
## PULLEY


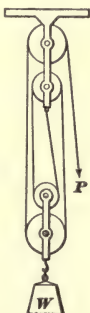
The *pulley* is simply another form of the lever that turns about a fixed axis or fulcrum. With a single fixed pulley, shown in Fig. 10, there can be no gain of power or speed, as the force $P$ must pull down as much as the weight $W$, and both move with the same velocity. It is simply a lever of the first class with equal arms, and is used to change the direction of the force. If $v$ = velocity of $W$; $v'$ = velocity of $P$; then $P = W$ and $v = v'$.

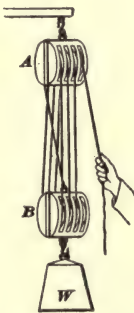
FIG. 10      FIG. 11

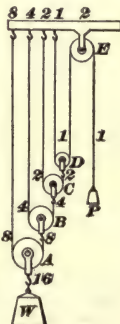
A form of the single pulley, where it moves with the weight, is shown in Fig. 11. In this, one-half of the weight is sustained by the hook, and the other half by the power. As the power is only one-half the weight, it must move through twice the space; in other words, by taking twice the time, twice as much can be raised. Here power is gained and time lost; therefore, $P = \frac{1}{2} W$ and $v' = 2v$.

**Combinations of Pulleys.**—(1) In Fig. 12, the weight $W$ is sustained by three cords, each of which is stretched by a tension equal to the $P$; hence,









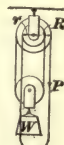


FIG. 12      FIG. 13      FIG. 14      FIG. 15      FIG. 16

1 lb. of power will balance 3 lb. of weight. (2) In Fig. 13, a power of 1 lb. will in the same manner sustain a weight of 4 lb., and must descend 4 in. to raise the weight 1 in. (3) Fig. 14 represents the ordinary tackle block used by mechanics, which can be calculated by the following general rule:

**Rule.**—*In any combination of pulleys where one continuous rope is used, a load on the free end will balance a weight on the movable block as many times as great as the load on the free end as there are parts of the rope supporting the load, not counting the free end.*

(4) In the cord marked *1*, Fig. 15, each part has a tension equal to the power $P$; and in the cord marked *2*, each part has a tension equal to *2 P*, and so on with the other cords. The sum of the tensions acting on the weight $W$ is 16; hence, $W = 16\,P$. If $n$ = number of pulleys,

$$P = \frac{W}{2^n} \qquad W = 2^n P$$

**Differential Pulley.**—In the differential pulley, shown in Fig. 16, $W = \dfrac{2\,P\,R}{R-r}$.

In all pulley combinations, nearly one-half the effective force is lost by friction.

## FALLING BODIES

When the center of gravity of a moving body passes over equal distances in equal intervals of time, the body has a *uniform motion;* otherwise, the motion is *variable.* The *velocity* in a uniform motion is constant and is equal to the distance traversed by the center of gravity of the body in a unit of time, as feet per second, miles per hour, etc. When, in a variable motion, the velocity increases or decreases uniformly with the time, the motion is designated, respectively, as *uniformly accelerated* or *uniformly retarded,* and, the rate of increase or decrease is called *acceleration* or *retardation,* being equal to the amount that the velocity increases or decreases in a unit of time. A body falling under the action of gravity is a case of uniformly accelerated motion, the acceleration being equal to 32.16 ft. per sec. and being usually denoted by $g$.

Let $\quad\quad\quad t$ = number of seconds that body falls;

$\quad\quad\quad\quad\quad v$ = velocity, in feet per second, at end of time $t$;

$\quad\quad\quad\quad\quad h$ = distance that body falls during time $t$.

Then, $\quad\quad\quad v = gt = \dfrac{2h}{t} = \sqrt{2gh} = 8.02\sqrt{h}$

$$h = \frac{vt}{2} = \frac{gt^2}{2} = \frac{v^2}{2g} = .015547v^2$$

$$t = \frac{v}{g} = \frac{2h}{v} = \sqrt{\frac{2h}{g}} = .24938\sqrt{h}$$

## WORK

*Work* is the overcoming of resistance through a distance. The unit of work is the *foot-pound;* that is, it equals 1 lb. raised vertically 1 ft. The amount of work done is equal to the resistance, in pounds, multiplied by the distance, in feet, through which it is overcome. If a body is lifted, the resistance is the weight, or the overcoming of the attraction of gravity, the work done being the weight $W$, in pounds, multiplied by the height $h$ of the lift, in feet, or $Wh$ ft.-lb.

*Power* is the amount of work performed in a unit of time. One horsepower is 550 ft.-lb. of work in 1 sec., 33,000 ft.-lb. in 1 min., 1,980,000 ft.-lb. in 1 hr. In the metric system, 1 H. P. is 75 meter-kilograms per second, usually written 75 m. Kg.-sec.

*Kinetic energy* is the capacity of a moving body to perform work. If the moving body has a weight $W$ and a velocity $v$, the work that it is capable of doing in being brought to rest is $\dfrac{Wv^2}{2g}$. A body falling through a height of $h$ ft. acquires during its fall a velocity of $v = \sqrt{2gh}$; its kinetic energy is therefore,

$$\frac{W(\sqrt{2gh})^2}{2g} = Wh$$

EXAMPLE 1.—What is the horsepower of a stream of water discharging 12 cu. ft. per sec. through a height of 125 ft.?

SOLUTION.—The kinetic energy per second, is $62.5 \times 12 \times 125$ ft.-lb., 62.5 being the weight of 1 cu. ft. of water. The horsepower is, therefore,

$$\frac{62.5 \times 12 \times 125}{550} = 170.5$$

EXAMPLE 2.—What is the kinetic energy per second of a jet of water whose area of cross-section is .1 sq. ft. and whose velocity is 10 ft. per sec.?

SOLUTION.—In this case, $W = 62.5 \times .1 \times 10 = 62.5$ lb. The kinetic energy is therefore, $\quad\quad \dfrac{62.5 \times 10^2}{2g} = \dfrac{6,250}{64.32} = 97.2$ ft.-lb. per sec.

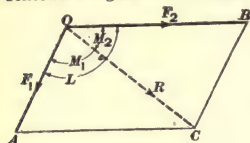
## COMPOSITION AND RESOLUTION OF FORCES

The *resultant* of two or several forces acting on a body is the single force that, if acting alone, would produce the same effect as the several forces combined. The latter forces are called *components* with respect to the resultant.

*Composition of forces* is the process of finding the resultant when the components are known, and the converse process of finding the components when the resultant is given, is called *resolution of forces.*

**Parallelogram of Forces.**—If two forces, as $F_1$ and $F_2$, Fig. 1, are represented in magnitude and direction by two lines, as $OA$ and $OB$, their resultant $R$

FIG. 1

will be represented in magnitude and direction by the diagonal $OC$ of the parallelogram $OACB$ which is constructed by drawing $BC$ and $AC$ parallel to $OA$ and $OB$, respectively, and joining the intersection $C$ with $O$.


The resultant $R$ can also be determined analytically: its magnitude by the formula $R = \sqrt{F_1{}^2 + F_2{}^2 - 2F_1F_2 \cos L}$, and the angles $M_1$ and $M_2$ that $R$ makes with $F_1$ and $F_2$, respectively, may be found by the formulas,

$$\sin M_1 = \frac{F_2 \sin L}{R}$$

and

$$\sin M_2 = \frac{F_1 \sin L}{R}$$

For *rectangular components*, $L = 90°$. The formulas then become:

$$R = \sqrt{F_1^2 + F_2^2}$$

$$\sin M_1 = \frac{F_2}{R}$$

$$\sin M_2 = \frac{F_1}{R}$$

FIG. 2

**Resolution of Forces.**—A given force may have an innumerable number of combinations of components. The problem is, however, determinate when the directions of the components are given. Let $OC$, Fig. 2, represent in magnitude and direction the force $R$ acting at $O$, and let it be required to find its components in the directions $OX_2$ and $OX_1$. Draw from $C$, lines parallel to these directions meeting $OX_1$ at $A$ and $OX_2$ at $B$. Then, $OA$ and $OB$ are the required components $F_1$ and $F_2$. They may also be determined analytically by the formulas,

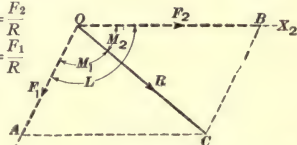
$$F_1 = \frac{R \sin M_2}{\sin (M_1 + M_2)}$$

and

$$F_2 = \frac{R \sin M_1}{\sin (M_1 + M_2)}$$

When $F_1$ and $F_2$ are perpendicular to each other, $M_1 + M_2 = 90°$ and

$$F_1 = R \sin M_2$$
$$F_2 = R \sin M_1$$

---


# MOMENTS OF FORCES

The *moment* of a force about a point is the product obtained by multiplying the magnitude of the force by the perpendicular distance from the point to the line of action of the force. In the accompanying figure, the moment of $F$ about the point $C$ is $Fp$; and about the point $C_1$ it is $Fp_1$.

The point to which a moment is referred, or about which a moment is taken is called the *center of moments*, or *origin of moments*. The perpendicular $p$ or $p_1$ from the origin of moments on the line of action of the force is called the *lever arm* or simply the *arm*, of the force with respect to the origin.

A moment is expressed in foot-pounds, inch-tons, etc., according to the units to which the force and its arm are referred.

The moment is either positive or negative, depending on the direction in which the force tends to cause rotation. It is positive for clockwise motion, and negative for counter-clockwise motion. Thus, the moment of $F$ about $C$ is positive and the moment about $C_1$ is negative, because, if the arms $p$ and $p_1$ were bars, the force would tend to rotate $p$ in a clockwise direction, and $p_1$ in a counter-clockwise direction.

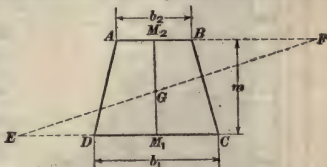
# CENTER OF GRAVITY

The *center of gravity* of a figure or a body is that point upon which the figure or the body will balance no matter in what position it may be placed, provided it is acted upon by no other force than gravity.

If a plane figure is alike, or symmetrical, on both sides of a center line, the latter line is termed an *axis of symmetry*, and the center of gravity lies in this line. If the figure is symmetrical about any other axis, the intersection of the two axes will be the center of gravity of the section; thus, the center of gravity of a *parallelogram* is at the intersection of the diagonals and that of a *circle* or an *ellipse* is at the geometrical center of the figure. The center of gravity of a *triangle* lies on a line drawn from a vertex to the middle point of the opposite side, and at a distance from that side equal to one-third the length of the line; or it is at the intersection of lines drawn from the vertexes to the middle points of the opposite sides.

FIG. 1

To find the center of gravity of a *trapezoid*, Fig. 1, lay off $BF = DC$ and $DE = AB$; the center of gravity is at the intersection of $EF$ with $M_1 M_2$, the line joining the middle points of the parallel sides. $GM_1$ can also be determined by the formula

$$GM_1 = \frac{m(b_1 + 2b_2)}{3(b_1 + b_2)}$$


The center of gravity of any *quadrilateral* may be determined as follows: First divide it, with a diagonal, into two triangles, and join with a straight line the centers of gravity of the two triangles; then, with the second diagonal, divide the figure into two other triangles and join the centers of gravity of these triangles with a straight line. The center of gravity of the quadrilateral is at the intersection of the lines joining the centers of gravity of the two sets of triangles.

For an *arc of a circle*, the center of gravity lies on the radius drawn to the middle point of the arc (an axis of symmetry) and at a distance from the center equal to the length of the chord multiplied by the radius and divided by the length of the arc.

For a *semicircle*, the distance from the center $= \frac{2r}{\pi} = .6366\,r$, when $r =$ radius.

For the area included in a *half circle*, the distance of the center of gravity from the center is

$$\frac{4r}{3\pi} = .4244\,r$$

For a *circular sector*, the distance of the center of gravity from the center equals two-thirds of the length of the chord multiplied by the radius and divided by the length of the arc.

For a *circular segment*, let $A$ be its area and $C$ the length of its chord; then the distance of the center of gravity from the center of the circle is equal to $\frac{C^3}{12A}$.

The center of gravity of any *irregular plane figure* can be determined by applying the following principle: The static moment of any plane figure with regard to a line in its plane—that is, the product of its area $A$ by the distance $D$ of its center of gravity from that line—is equal to the algebraic sum of the static moments of the separate parts into which the figure may be divided, with regard to the same axis, or

$$AD = a_1d_1 + a_2d_2, \text{ etc.},$$

in which, $a_1$, $a_2$, etc., denote the areas of the subdivided parts of the figure, and $d_1$, $d_2$, etc. are the distances of their respective centers of gravity from the reference line. Solving this equation for the value of $D$,

$$D = \frac{a_1d_1 + a_2d_2 + \text{etc.}}{A}$$

The figure whose center of gravity is required is divided into separate parts whose centers of gravity are easily ascertained, usually into rectangles or triangles. A suitable axis is then assumed with reference to which the expressions $a_1d_1$, $a_2d_2$, etc. are found, and their sum is divided by $A = a_1 + a_2 + \text{etc.}$, the quotient giving $D$. The center of gravity of the whole figure lies, therefore, on a line parallel to the assumed axis and distant $D$ from it. In a similar manner,

another line containing the center of gravity is obtained, the intersection of the two lines giving its exact position.

**EXAMPLE 1.**—Find the center of gravity of the cross-section of the dam shown in Fig. 2.

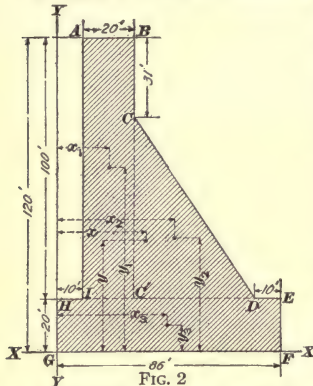


FIG. 2

SOLUTION.—Divide the section into the rectangles $ABC'I$ and $HEFG$ and the triangle $CDC'$, and assume the lines $X-X$ and $Y-Y$ as reference lines. Then,

$$y = \frac{a_1 y_1 + a_2 y_2 + a_3 y_3}{a_1 + a_2 + a_3}$$

and

$$x = \frac{a_1 x_1 + a_2 x_2 + a_3 x_3}{a_1 + a_2 + a_3}$$

From the illustration, $a_1 = 100 \times 20$ $= 2,000$, $y_1 = 70$, $x_1 = 20$; $a_2 = \dfrac{69 \times 46}{2}$ $= 1,587$, $y_2 = 43$, $x_2 = 45.33$; $a_3 = 86 \times 20$ $= 1,720$, $y_3 = 10$, and $x_3 = 43$. Substituting these values,

$$y = \frac{2,000 \times 70 + 1,587 \times 43 + 1,720 \times 10}{2,000 + 1,587 + 1,720}$$
$$= 42.48$$
$$x = \frac{2,000 \times 20 + 1,587 \times 45.33 + 1,720 \times 43}{5,307}$$
$$= 35.03$$

**EXAMPLE 2.**—Find the center of gravity of the bridge chord section shown in Fig. 3.

SOLUTION.—The center of gravity is on the line $YY$, which is an axis of symmetry. To find the distance $y$, divide the section into angles and plates and take moments about $XX$. The areas and centers of gravity of the angles might be located by the preceding principles or taken from a manufacturer's handbook. They are: For the $4'' \times 4'' \times \frac{1}{2}''$ angle, area $= 3.75$ sq. in. and distance from center of gravity to back of angle $= 1.18$ in.; for the $3\frac{1}{2}'' \times 3\frac{1}{2}'' \times \frac{1}{2}''$ angle, area $= 3.25$ sq. in. and distance from center of gravity to back of angle $= 1.06$ in. Hence, the moment of the bottom angles is $2 \times 3.75 \times 1.18 = 8.85$ and that of the top angles is $2 \times 3.25 \times (15 - 1.06) = 90.61$. The moment of the two web-plates is $2 \times 15 \times \frac{1}{2} \times 7.5 = 112.5$, and that of the cover-plate, $24 \times \frac{1}{2} \times 15.25 = 183.00$. The sum of the moments is, $8.85 + 90.61 + 112.5 + 183.00 = 394.96$. The sum of the areas is $2 \times 3.25 + 2 \times 3.75 + 24 \times \frac{1}{2} + 2 \times 15 \times \frac{1}{2} = 41$ sq. in. Then, $y = 394.96 \div 41 = 9.63$ in.

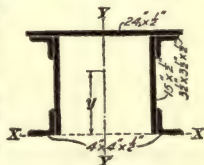
FIG. 3

**Center of Gravity of Solids.**—For a solid having three axes of symmetry, all perpendicular to each other, like a sphere, cube, right parallelopiped, etc., the point of intersection of these axes is the center of gravity.

For a cone or pyramid, draw a line from the apex to the center of gravity of the base; the required center of gravity is one-fourth the length of this line from the base, measured on the line.

For two bodies, the larger weighing $W$ lb., and the smaller $P$ lb., the center of gravity will lie on the line joining the centers of gravity of the two bodies and at a distance from the larger body equal to $\dfrac{Pa}{P+W}$, where $a$ is the distance between the centers of gravity of the two bodies.

For any number of bodies, first find the center of gravity of two of them, and consider them as one weight whose center of gravity is at the point just found. Find the center of gravity of this combined weight and a third body. So continue for the rest of the bodies, and the last center of gravity will be the center of gravity of the whole system of bodies.

To find the center of gravity mechanically, suspend the object from a point near its edge and mark on it the direction of a plumb-line from that point; then suspend it from another point and again mark the direction of a plumb-line. The intersection of these two lines will be directly over the center of gravity.


## MOMENT OF INERTIA

The *moment of inertia* of a plane surface about a given axis is the sum of the products obtained by multiplying each of the elementary areas, into which the surface may be conceived to be divided, by the square of its distance from the axis.

### MOMENTS OF INERTIA, ETC.

| Name of Section | | $I$ | $\dfrac{I}{c}$ | $r^2$ |
|---|---|---|---|---|
| Solid circular | | $\dfrac{\pi d^4}{64}$ | $\dfrac{\pi d^3}{32}$ | $\dfrac{d^2}{16}$ |
| Hollow circular | | $\dfrac{\pi(d^4-d_1^4)}{64}$ | $\dfrac{\pi(d^4-d_1^4)}{32d}$ | $\dfrac{d^2+d_1^2}{16}$ |
| Solid square | | $\dfrac{d^4}{12}$ | $\dfrac{d^3}{6}$ | $\dfrac{d^2}{12}$ |
| Hollow square | | $\dfrac{d^4-d_1^4}{12}$ | $\dfrac{d^4-d_1^4}{6d}$ | $\dfrac{d^2+d_1^2}{12}$ |
| Solid rectangular | | $\dfrac{bd^3}{12}$ | $\dfrac{bd^2}{6}$ | $\dfrac{b^2}{12}$ |
| Hollow rectangular | | $\dfrac{bd^3-b_1d_1^3}{12}$ | $\dfrac{bd^3-b_1d_1^3}{6d}$ | $\dfrac{b^3d-b_1^3d_1}{12(bd-b_1d_1)}$ |
| Solid triangular | | $\dfrac{bd^3}{36}$ | $\dfrac{bd^2}{24}$ | $\dfrac{d^2}{18}$ |
| Solid elliptic | | $\dfrac{\pi bd^3}{64}$ | $\dfrac{\pi bd^2}{32}$ | $\dfrac{b^2}{16}$ |
| Hollow elliptic | | $\dfrac{\pi}{64}(bd^3-b_1d_1^3)$ | $\dfrac{\pi(bd^3-b_1d_1^3)}{32d}$ | $\dfrac{b^3d-b_1^3d_1}{16(bd-b_1d_1)}$ |
| I-beam | | $\dfrac{bd^3-b_1d_1^3}{12}$ | $\dfrac{bd^3-b_1d_1^3}{6d}$ | $\dfrac{b^3d-b_1^3d_1}{12(bd-b_1d_1)}$ |
| Cross with equal arms (approximate) | | | | $\dfrac{d^2}{22.5}$ |
| Angle with equal arms (approximate) | | | | $\dfrac{d^2}{25}$ |

The moment of inertia is usually designated by the letter $I$. The value of the moment of inertia used in calculating the strength of beams and columns is usually taken about the neutral axis of the figure, which, with the exception of reinforced-concrete sections, passes through the center of gravity of the figure.

Formulas for the values of $I$ about an axis passing through the center of gravity of the section are given for various forms of sections in the

accompanying table. For any other section, it can be computed by means of the following principles:

**Principle I.**—*The moment of inertia of a section about any axis is equal to the algebraic sum of the moments of inertia about the same axis, of the separate parts of which the figure may be conceived to consist.*

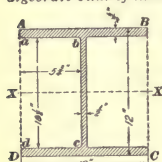


FIG. 1

**Principle II.**—*The moment of inertia of any figure about an axis not passing through the center of gravity, is equal to the moment of inertia about a parallel axis through the center of gravity, plus the product of the entire area of the section by the square of the distance between the two axes.*

EXAMPLE 1.—Find the moment of inertia about the neutral axis

FIG. 2

$XX$ of the Bethlehem **I** column section having dimensions as shown in Fig. 1.

SOLUTION.—Conceive the section to consist of the square $ABCD$ minus twice the rectangle $abcd$. Then, by applying principle I and the formulas of the table for moments of inertia.

$$I = \frac{12^4}{12} - \frac{2 \times 5.75 \times 10.5^3}{12} = 618.6$$

NOTE.—This result can be obtained directly by the **I**-beam formula, given in the same table.

EXAMPLE 2.—Find the moment of inertia of the section shown in Fig. 2 about the neutral axis parallel to the cover-plate.

SOLUTION.—The neutral axis passes through the center of gravity, which has been found to be 9.63 in. from the back of the bottom angles. The distances of the centers of gravity of the subdivisions of this section from the axis $XX$, Fig. 2, are:

For the cover-plate $15.25 - 9.63$ . . . . . . . . . . . . . . . . . . . . . . . . . . . . $= 5.62$
For the web-plates $9.63 - 7.50$ . . . . . . . . . . . . . . . . . . . . . . . . . . . $= 2.13$
For the $3\frac{1}{2}'' \times 3\frac{1}{2}'' \times \frac{1}{2}''$ **L**'s, $15.00 - 1.06 - 9.63$ . . . . . . . . . . . $= 4.31$
For the $4'' \times 4'' \times \frac{1}{2}''$ **L**'s, $9.63 - 1.18$ . . . . . . . . . . . . . . . . . $= 8.45$

The moments of inertia of the respective parts about their own neutral axes parallel to $XX$ are:

For the cover-plate . . . . . . . . . . . . . . . . . . . . . . . $\dfrac{24 \times (\frac{1}{2})^3}{12} =$    $.25$

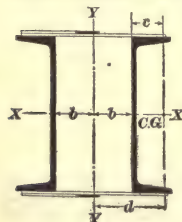
For the web-plates . . . . . . . . . . . . . . . . . . . . . . . $\dfrac{2 \times \frac{1}{2} \times 15^3}{12} = 281.25$

From a steel manufacturer's handbook, the value of $I$ for a $3\frac{1}{2}'' \times 3\frac{1}{2}'' \times \frac{1}{2}''$ **L** is found to be 3.64; and for a $4'' \times 4'' \times \frac{1}{2}''$ **L** it is 5.56. Applying principle II, the moment of inertia of the entire section is, $I = .25 + 24 \times \frac{1}{2} \times 5.62^2 + 281.25 + 2 \times 15 \times \frac{1}{2} \times 2.13^2 + 2 \times 3.64 + 2 \times 3.25 \times 4.31^2 + 2 \times 5.56 + 2 \times 3.75 \times 8.45^2$
$= 1,403.22$.

## RADIUS OF GYRATION

Let $I$ denote the moment of inertia of any section and $a$ its area; then, the relation between $I$ and $a$ is expressed in the formula, $I = ar^2$, in which $r$ is a constant depending on the shape of the section and is called the *radius of gyration* of the section referred to the same axis as $I$. Then,

FIG. 3

$$r = \sqrt{\frac{I}{a}}.$$


EXAMPLE 1.—What is the radius of gyration of the section shown in Fig. 1 about the axis $XX$?

SOLUTION.—The moment of inertia of this section has been found to be 618.6 and its area is $2 \times 12 \times \frac{3}{4} + 10.5 \times \frac{1}{2} = 23.25$ sq. in. Substituting in the formula,

$$r = \sqrt{\frac{618.6}{23.25}} = 5.16$$

EXAMPLE 2.—Determine the distance $b$ in the strut made up of two latticed channels, as shown in Fig. 3, so that the radii of gyration about the axes $XX$ and $YY$ will be equal.

SOLUTION.—Let $I_x$, $r_x$, $I_y$, $r_y$ be, respectively, the moments of inertia and radii of gyration of a single ⅃ about the axes $XX$ and $YY$; $a$ its area and $CG$, its center of gravity, then, from the figure, $b = d - c$, and $I_x = ar_x^2$; also, $I_y = ar_y^2 + ad^2$. Hence, by the condition of the problem, $ar_x^2 = ar_y^2 + ad^2$, or $r_x^2 = r_y^2 + d^2$. Whence, $d = \sqrt{r_x^2 - r_y^2}$. The values of $r_x$, $r_y$ and $c$ for any ⅃ may be taken from a steel manufacturer's handbook. For instance, for a 15-in. ⅃ of 33 lb. $r_x = 5.62$, $r_y = .912$, and $c = .794$; hence, $d = \sqrt{5.62^2 - .912^2} = 5.546$, and $b = d - c = 5.546 - .794 = 4.752$.

A practical rule giving good approximate results for a channel column or strut is to subtract $r_y$ from $r_x$; the result is $b$. Applying this rule to the 15-in. ⅃ of 33 lb. column or strut, $b = 5.62 - .912 = 4.708$.

## SECTION MODULUS AND MOMENT OF RESISTANCE

The expression $\dfrac{I}{c}$, in which $I$ is the moment of inertia and $c$ the distance of the outermost fiber of the section from the neutral axis, is called the *section modulus*. For a given material, this quantity is a measure of the capacity of the section to resist bending. Multiplied by the unit stress to which the outermost fibers are subjected under given loads, the product gives the amount of bending moment the section is resisting, and is called *moment of resistance*. If $f$ is the unit stress that certain loads develop in the outermost fibers of the section, the moment of resistance is

$$M_r = \frac{I}{c} f$$

EXAMPLE 1.—What is the section modulus of a 20-in. I beam of 75 lb. whose moment of inertia is 1,268.9?

SOLUTION.—As the neutral axis passes through the center of the section, the distance $c$ is in this case equal to one-half the depth; that is $20 \div 2 = 10$. The section modulus is therefore $\dfrac{I}{c} = \dfrac{1,268.9}{10} = 126.9$

EXAMPLE 2.—When subjected to loads perpendicular to the cover-plates the outermost fibers of the section shown in Fig. 2, are stressed to 16,000 lb. per sq. in. What is the resisting moment of the section?

SOLUTION.—The moment of inertia of the section has been found to be 1,403.22, and the outermost fibers are 9.63 in. from the neutral axis; hence, the section modulus is equal to $1,403.22 \div 9.63 = 145.7$; this multiplied by 16,000 gives 2,331,200 in.-lb.

Formulas for obtaining directly the section moduli of sections frequently used are given in the table of Moments of Inertia, etc.

## FRICTION

*Friction* is the resistance that a body meets from the surface on which it moves. It depends on the degree of roughness of the surfaces in contact, and is directly proportional to the perpendicular pressure between the surfaces. It is independent of the extent of the surfaces in contact as long as the normal pressure remains the same. It is generally greater between surfaces of the same material than between those of different materials, and greater between soft bodies than hard ones.

**Coefficient of Friction.**—The ratio between the resistance to the motion of a body due to friction and the perpendicular pressure between the surfaces is called the *coefficient of friction*. When the coefficient of friction between two surfaces is known, the frictional resistance is obtained by multiplying the normal pressure by the coefficient.

EXAMPLE 1.—What is the resistance per linear foot of a retaining wall against sliding when the normal pressure on the foundation is 10,000 lb. per lin. ft. of wall and the coefficient of friction of the masonry on the foundation is .65?

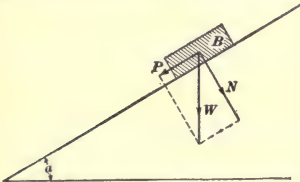
SOLUTION.—The frictional resistance is $10,000 \times .65 = 6,500$ lb.

The coefficient of friction of the wheels of suddenly stopping engines and cars on the rails is usually assumed at .20. The rails on bridges or trestles will transfer to the bridge or trestle tower the frictional forces produced by the brakes in order to stop the cars, causing stresses that must be provided for.

EXAMPLE 2.—What is the longitudinal force on a bridge caused by the sudden stopping of a car weighing 60,000 lb?

SOLUTION.—The longitudinal force will be $60,000 \times .20 = 12,000$ lb.

**Angle of Friction.**—When a body, as $B$ in the accompanying illustration, weighing $W$ lb. is placed on an inclined plane making an angle $a$ with the horizontal, the normal pressure is $N = W \cos a$; and, if the coefficient of friction is denoted by $f$, the frictional resistance against sliding down of the body is



$F = fN = fW \cos a$. This force acts in a direction opposite to that of the force $P = W \sin a$. When the angle $a$ is such that $F$ just balances, or is equal to $P$, so that the slightest force will cause the body to slide, the angle is then called the *angle of friction*. The tangent of that angle is equal to the coefficient of friction, or $f = \tan a$.

**Angle of Repose.**—On a sloping bank of loose material, such as sand, earth, etc., when the angle of slope is such that the particles are on the point of moving, the angle is called the *angle of repose*. It is the same as the angle of friction of the material on itself. The slope is then called the *slope of repose*, or the *natural slope of the material*, for it is the slope that the material will assume when subject to gravity only.

EXAMPLE.—The coefficient of friction of dry sand on itself is .65; what is its angle of repose?

SOLUTION.—The angle of repose is the same as the angle of friction, whose tangent equals the coefficient of friction; consequently, $.65 = \tan a$, and from a table of natural tangents $a = 33°$.

The accompanying tables give coefficients of friction and angles of repose of a number of materials.

**COEFFICIENTS OF FRICTION AND ANGLES OF REPOSE FOR MASONRY MATERIALS**

| Material | Coefficient of Friction | Angle of Repose Degrees |
|---|---|---|
| Fine-cut granite, on same, dry | .60 | 31 |
| Fine-cut granite, on rough-pointed granite, dry | .65 | 33 |
| Rough-pointed granite, on same, dry | .70 | 35 |
| Well-dressed soft limestone, on same, dry | .75 | 37 |
| Concrete blocks, on same, dry | .65 | 33 |
| Concrete blocks, on fine-cut granite, dry | .60 | 31 |
| Common brick, on same, dry | .65 | 33 |
| Common brick, on well-dressed soft limestone, dry | .65 | 33 |
| Common brick, on well-dressed hard limestone, dry | .60 | 31 |
| Common brick, on same, with slightly damp mortar | .75 | 37 |
| Hard brick, on same, with slightly damp mortar | .70 | 35 |
| Hard limestone, on same, with slightly damp mortar | .65 | 33 |
| Common brick, on same, with fresh mortar | .50 | 27 |
| Well-dressed granite, on same, with fresh mortar | .50 | 27 |
| Granite, roughly worked, on dry sand and gravel | .50 to .60 | 27 to 31 |
| Granite, roughly worked, on wet sand | .35 to .45 | 19 to 24 |
| Granite, roughly worked, on dry clay | .50 | 27 |
| Granite, roughly worked, on moist clay | .35 | 19 |

**Rolling Friction.**—The friction between the circumference of a rolling body and the surface upon which it rolls is known as *rolling friction*. It is due to the compressibility of substances, the weight of the rolling body causing a small depression in the supporting surface and a flattening of the roller. Its magnitude depends on the materials of the roller and the supporting surface, and is proportional to the normal pressure exercised by the roller on the rolling surface. It depends also on the diameter of the roller, being less for large rollers

than for small ones. On highways with soft compressible surfaces, the resistance is also affected by the width of the wheel tires, being greater for narrow tires than for wide ones.

## COEFFICIENTS OF FRICTION, ANGLES OF REPOSE, AND WEIGHTS OF EARTHS

| Material | Coefficient of Friction | Angle of Repose Degrees | Weight Pounds per Cubic Foot |
|---|---|---|---|
| Mixed earth, dry | .70 | 35 | 95 |
| Mixed earth, damp | .80 | 39 | 115 |
| Mixed earth, wet | .40 | 22 | 115 |
| Sand, dry | .65 | 33 | 110 |
| Sand, wet | .05 | 3 | 125 |
| Loam, dry | .70 | 35 | 75 to 100 |
| Loam, wet | .50 | 27 | 90 to 120 |
| Clay, dry | 1.00 | 45 | 100 |
| Clay, wet | .30 | 17 | 125 |

## COEFFICIENTS AND ANGLES OF FRICTION FOR MISCELLANEOUS MATERIALS

| Materials | Coefficient of Friction | Angle of Friction Deg. Min. | |
|---|---|---|---|
| Cast iron on cast iron | .15 | 8 | 32 |
| Cast iron on brass | .15 | 8 | 32 |

| Leather packing | .56 | 29 | 15 |

The first table on page 162 gives the maximum, minimum, and mean values of the coefficient of rolling friction for different roadway surfaces. They are expressed in pounds required to overcome the resistance on a level road of a gross ton (2,240 lb.). The mean value is also expressed as a ratio between the frictional resistance and the load.

The friction of liquids moving in contact with solid bodies is independent of the pressure, because the forcing of the particles of the fluid over the

projections on the surface of the solid body is aided by the pressure of the surrounding particles of the liquid, which tend to occupy the places of those

## ROLLING FRICTION FOR DIFFERENT ROADWAY SURFACES

| Character of Roadway Surface | Rolling Friction | | | |

| Asphalt..................... | 39 | 15 | 22 | $\frac{1}{100}$ |

forced over. Therefore, the coefficients of friction of liquids over solids do not correspond with those of solids over solids. The resistance is directly as the area of surface or contact.

## COEFFICIENTS OF FRICTION IN AXLES

| Axle | Bearing | Ordinary Lubrication | Lubricated Continuously |
| --- | --- | --- | --- |
| Bell metal......... | Bell metal ....... | .097 | |
| Cast iron.......... | Bell metal ....... | .07 | .049 |
| Wrought iron....... | Bell metal....... | .07 | .05 |
| Wrought iron....... | Cast iron........ | .07 | .05 |
| Cast iron.......... | Cast iron........ | .07 | .05 |
| Cast iron.......... | Lignum vitæ...... | .10 | |
| Wrought iron....... | Lignum vitæ...... | .12 | |

Friction naturally varies with the character of the surfaces, lubrication, and the nature of the lubricant. The best lubricants for the purposes should always be used, and the supply should be regular. When machinery is well lubricated, the lubricant keeps the surfaces apart, and the frictional resistance becomes very small, or about the same as the friction of liquids.

**Frictional Resistance of Shafting.—**

Let    $K$ = coefficient of friction;
       $W$ = work absorbed, in foot-pounds;
       $P$ = weight of shafting and pulleys + resultant stress of belts;
       $H$ = horsepower absorbed;
       $D$ = diameter of journal, in inches;
       $R$ = number of revolutions per minute.

| Then, | ORDINARY OILING | CONTINUOUS OILING |
|---|---|---|
| | $W = .0182PD$ | $.0112PD$ |
| | $H = .000000556PDR$ | $.000000339PDR$ |
| | $K = .066$ | $.044$ |

As a rough approximation, 100 ft. of shafting, 3 in. diameter, making 120 rev. per min., requires 1 H.P.

For friction of air in mines, see Coefficient of Friction, under Ventilation.

**Friction of Mine Cars.**—The friction of mine cars varies so much that it is impossible to give a formula for calculating it in every case. No two mine cars will show the same frictional resistance, when tested with a dynamometer, and, therefore, nothing but an average friction can be dealt with. The construction of the car, the condition of the track, and the lubrication are important factors in determining the amount of friction.

Some of the requisites of good oil box and journal bearings may be stated. Tightness is a prerequisite, and, in dry mines where the dust is very penetrating, this is especially important; the bearings should be sufficiently broad; the oil box large enough to hold sufficient oil to run 1 mo. without renewal, and so constructed that, while it may be quickly and easily opened, it will not open by jarring or by being accidentally struck by a sprag or a lump of coal.

There are a number of patented self-oiling wheels that are improvements on the old-style plain wheels, and each of these has undoubtedly some point of superiority over the old style.

Among the most extensively used of these patented wheels are those with annular oil chambers, and those with patent bushings. Their superiority consists in the fact that, if properly attended to, a well-lubricated bearing is secured with greater regularity and less work than when the old-style wheel is used.

With a view of adopting a standard wheel, the Susquehanna Coal Co., of Wilkes-Barre, Pa., experimented for a number of years with different styles of self-lubricating wheels.

Mr. R. Van A. Norris, E. M., assistant engineer, made a series of 989 tests with old-style wheels, some of which had patent removable bushings, and others annular oil chambers, and the self-oiling wheel. The old wheels were found to be practically alike in regard to friction. All the wheels were of the loose outside type, 16 in in diameter, mounted on 2⅜ in. steel axles, with journals 5¼ in. long. The axles passed loosely through solid cast boxes, bolted to the bottom sills of the cars, and were not expected to revolve.

The table of friction tests shows the results obtained with both old- and new-style wheels, and is of interest to all colliery managers, inasmuch as the figures given for the old-style wheels alone are the most complete in existence and, as stated before, they are good averages.

Tests were made on the starting and running riction of each style of wheel, under the conditions of empty and loaded cars level and grade track, curves, and tangents. The instruments were a Pennsylvania Railroad spring dynamometer, graduated to 3,000 lb., with a sliding recorder, a hydraulic gauge (not recording) reading to 10,000 lb., graduated to 25 lb , and a spring balance, capacity 300 lb., graduated to 3 lb. All these were tested and found correct previous to the experiments.

Most of the observations on single cars were made with the 300-lb. balance. The two types of old-style wheels have been classed together in the table. Each car was carefully oiled before testing, and several of each type were used, the results being averages from the number of trials shown in the table.

In the experiments on the slow start and motion, the cars were started very slowly by a block and tackle, and the reading was taken at the moment of starting. They were then kept just moving along the track for a considerable distance, and the average tractive force was noted, the whole constituting one experiment.

The track selected for these experiments was a perfectly straight and level piece of 42 in. gauge, about 200 ft. long, in rather better condition than the average mine track. The cars were 41¾ in. gauge, 3½ ft. wheel base, 10 ft. long, capacity about 85 cu. ft., with 6-in. topping.

To ascertain the tractive force required at higher speeds, trips of one, four and twenty cars, both empty and loaded, were attached to a mine locomotive and run about 1 mi. for each test, the resistance at various points on the track, where its curve and grade were known, being noted, care also being taken to run at a constant speed. Unfortunately, only four of the new-style cars were available on the tracks where these trials were made.

The remarkably low results for the twenty-car trips are attributed to variations in the condition of the track, and the fact that the whole train

## SUMMARY OF FRICTION TESTS ON OLD-STYLE MINE-CAR WHEELS

was seldom pulling directly on the locomotive, the cars moving by jerks, so that correct observations were impracticable. The hydraulic gauge was used for these twenty-car tests, and the needle showed vibrations from 1 to 4 T. and back. The mean was taken as nearly as possible. The gauge was rather too quickly sensitive for the work, and the Pennsylvania Railroad dynamometer was not strong enough to stand the starting jerks and the strain of accelerating speed.

The tests marked Rope Haul were made on an empty-car haulage system, about 500 ft. long, with overhead endless rope running continuously at a speed of 180 ft. per min., the cars being attached to the moving rope by a chain, a ring at the end of which was slipped over a pin on the side of the car. The increase of friction on the heavier grades was due to the rope pulling at a greater angle across the car. Correction was not made for this angularity at the time, and the rope has since been rearranged, so that the correction cannot now be made. There were not enough curve experiments to permit the deduction of any general formula for the resistance of these cars on curves.

The experiments on grade agree fairly well with those on a level, the rather higher values obtained being probably due more to the greater effort required in moving them, and the consequent jerkiness of the motion, than to any real increase in resistance. As the experiments on all styles of wheels were made in an exactly similar manner, the comparative value of the results is believed to be nearly correct, the probable error in each set of experiments, as computed by the method of least squares, varying from about 4% for slow start and motion to 12% for the rapid motion and twenty-car trips.

**Ball and Roller Bearings.**—Some of the leading manufacturers now provide mine-car wheels with either ball or roller bearings. In the former type, a series of steel balls placed within the hub bear upon the axle; and in the latter type, a series of steel rollers. In other features, however, such as the method of lubrication, etc., the improved wheels are essentially the same as the old. Only a limited number of tests have thus far been published upon the savings effected by the use of these improved bearings in power-transmission shafting, mine-car wheels, etc., but these indicate a diminution of from 15 to 75% in the friction over the old type of bearings. In the case of mine cars, those equipped with the new type of bearing require about one-half the drawbar pull formerly demanded either to start them from rest or to continue them in motion.

Quoting from one of the leading manufacturers of spiral roller bearings: "The saving in power varies to a certain extent with conditions. In some cases it has run as high as 60%; in others, it has been as low as 30%; a safe average saving is 40% to 50%. The following series of tests was made in November, 1912. The twenty-five cars used in the test had been in constant use for about 6 mo.; the wheels were 16 in. and the axles $2\frac{1}{4}$ in. in diameter.

| Type of Wheel | Average Starting Pull Pounds | Average Constant Pull Pounds | Gross Weight Pounds | Up-Grade Per Cent. | Constant Tractive Effort Per Ton Pounds | Tractive Effort Per Ton, Corrected For Level Pounds |
|---|---|---|---|---|---|---|
| Plain | 297 | 120 | 5,800 | .25 | 41.3 | 26.8 |
| Spiral } Roller } | 104 | 80 | 5,800 | .25 | 27.5 | 13.0 |

**Lubrication.**—There is probably no factor that has a more direct bearing on the cost of production per ton of coal and ores than the lubrication of mine machinery, and yet it is doubtful if there is another item connected with the operation of a mine less understood by owners, their managers, and engineers in charge.

Steam plants are equipped with boilers of the highest known efficiency; heaters are used that, by utilizing waste steam, will heat the feedwater for boilers to the highest point. Modern engines that will develop a horsepower with the least amount of steam are installed; bends, instead of elbows, are placed in steam and exhaust pipes, so that the friction and back pressure may be reduced to a minimum. In a word, everything is done in the equipment of a plant to secure economy in its operation. After all this is done,

frequently a long step is taken in the opposite direction by the use of an oil unsuited to the existing conditions, and those in charge of the plant are led to believe that the lubrication is all that could be desired, simply because the engines and machinery run quietly and the temperature of the bearings does not become alarmingly high. The office of a lubricant is not merely to secure this result, but, primarily, to reduce friction and wear to a minimum; and an oil that will do this is the best oil to use, no matter what the price per gallon may be.

Few realize the great loss in power due to the friction of wearing parts. One of the greatest living authorities on lubrication writes:

"It may probably be fairly estimated that one-half the power expended in the average case, whether in mill, mine, or workshop, is wasted on lost work, being consumed in overcoming the friction of poorly lubricated surfaces."

He adds that a reduction of 50% in the work lost by friction has often been secured by a change of lubricants.

As one of many instances showing the loss that will occur by the use of inferior lubricants, attention is called to two flour mills located in one of the Middle States. One of the plants was equipped with a condensing engine capable of developing 1 H. P. on 24 lb. of water per hr.; the other plant had a simple engine, taking 30 lb. of water per hr. The plant containing the condensing engine was purchased by the owner of the plant containing the simple engine. The new owner of the plant was surprised to learn that the cost of operation per barrel of flour manufactured was equally as great in the new plant as in the old one. The engines were indicated, and valves found to be properly adjusted and the engine working within the economical range, so far as load was concerned. The loss was then attributed to the boilers, but an evaporative test proved that there was no practical difference here, as the boilers, in both instances, were evaporating a fraction over 8 lb. of water per lb. of coal. At this point, the question of lubrication was taken up, and, on the advice of an expert sent by a prominent manufacturer of lubricants to look over the plant, an entire change was made in the lubricants used, and, as a result, a money saving of over $2.25 per da. (practically $700 per annum — this in a plant of less than 250 H. P.) was effected, notwithstanding the fact that the new lubricants used cost considerably more per gallon than those formerly used. This simply indicates that the price of an oil is of little importance in comparison with its friction-reducing power. Friction costs money, because it means greater cost of operation per unit of output.

Among the expenses chargeable to waste power, due to inferior lubrication, may be included: (1) The cost of power produced in excess of that really required to operate the mine per ton of output. In this calculation should be included the proper proportion of salaries of engineers, and all other items that contribute to the cost of the motive department, as well as the cost of mining the fuel consumed in producing this excess power. (2) Wear and tear of machinery, which is constantly doing more work per ton of coal mined than should be required of it.

There is also an element of danger that ought to receive serious consideration, as, while it is true that cylinder and bearing lubricants of indifferent merit will, under ordinary conditions, keep the cylinders from groaning and the bearings from becoming hot, experiments have proved that, in accomplishing such results, the oils in use were being taxed to their utmost; and there is record of many instances where, as a result of using oils of such limited endurance, accidents of a serious nature have occurred, necessarily causing shut-downs just at the time when the operation of the plant to its fullest capacity was imperative. It is most difficult to do much more than point out the danger due to the use of inferior lubricants, leaving it to the purchaser himself to determine as to the intrinsic worth of the lubricants offered to him. In making his selection he would do well to consult with and heed the advice of some highly responsible manufacturer of lubricants who has given to the question, in all its phases, the most careful study, and who would most probably have the benefit of a wide experience in the application as well as the manufacture of lubricants. Some buyers have, to their ultimate regret, adopted, as a method of determining the merits of lubricants, a schedule of laboratory tests. Such a method is not only useless, but it is misleading to any one other than a manufacturer of lubricants, who makes use of it merely as a means of insuring uniformity in his manufactured products, and not as a measure whereby to judge their practical value. Indeed, many oils can be very properly described by practically the same schedule of tests, and yet are widely apart when their utility for a given service is considered.

As a general guide in purchasing cylinder oil for mine lubrication, it might be said that a dark-colored oil is of greater value, as a rule, than one that has been filtered to a red or light amber color, as the process of filtration necessarily takes from the oil a considerable percentage of its lubricating value, and at the same time the process is an expensive one. In short, if a light-colored oil is insisted upon, a high price must be paid for an inferior lubricant. As a word of caution, however, it would be well to add right here that irresponsible manufacturers frequently take advantage of the fact that the most efficient and best known cylinder oils are dark-colored, and endeavor, with more or less success, to market as "cylinder oil" products absolutely unsuited to the lubrication of steam cylinders, and that would consequently be expensive could they be procured without cost.

For the lubrication of engine bearings, where modern appliances for feeding are used, an engine oil of a free running nature is best, as it more quickly reaches the parts requiring lubrication than an oil of a more sluggish nature. It, of course, must not be an oil susceptible to temperature changes, but must be capable of performing the service required of it under the most severe conditions, where an oil of less backbone would fail. Such an oil would also be suitable for the lubrication of dynamos, and should also give satisfaction where used in lubricating the cylinders of air compressors. Where the machinery is of an old type and loose-jointed, or when the bearings are open and the oil is applied directly to them by means of an oiler, an engine oil of a more sluggish, or viscid, nature is best.

Perhaps of equal importance to the lubrication of power machinery must be considered the lubrication of the axles of mine cars. This is important, first, because of the fact that perhaps three-fourths of the oil used about a coal mine is used for this purpose, and, secondly, because there is really a marked difference in the quality and, therefore, in the efficiency of lubricants used for this purpose. Fully nine-tenths of the prominent railroads of this country are today using car-axle oil, costing perhaps as much per gallon as much of the so-called cylinder oil that is used in coal mines, they having discovered, by exhaustive experiments, that the increased efficiency gained by using an oil of such quality many times offsets the difference in the cost per gallon and enables them to secure a greater mileage without any increase in their power or other fixed charges. This will apply just as forcibly to the lubrication of coal cars, no matter whether the power is derived from mules or electric motors; therefore, this feature of lubrication of mine equipment should receive more careful attention than it does receive, as a rule.

There is considerable waste in the lubrication of mine cars. This waste is hard to avoid, and, naturally, makes the buyer hesitate before adopting the use of a car oil that costs very much per gallon; but even in the face of this waste the increased efficiency secured by the use of a high-grade car oil will warrant its use. Such waste is pretty hard to correct in mines where the old-fashioned style of car axle is still in use, and where the oil is applied through an ordinary spout oil can into the axle box, and allowed to drip off the axles and on to the ground. When axles are equipped in the same manner as those of freight cars, or where cars are equipped with one of the several different styles of patent car wheels and axles that are coming into use quite extensively, it is possible to regulate the feeding of the oil to the axles, so as to reduce the waste to a minimum. One of these patent car wheels, which is perhaps better known than any other, is constructed with a hollow hub that acts as a reservoir for the oil, the oil passing from this reservoir through small holes on to a felt washer, which it must saturate, and by which it is applied to the axles. Such wheels require a limpid oil, as a heavy, sluggish oil will not so readily saturate the felt washer referred to. A tight cap is adjusted to the end of the axle, to prevent waste of oil. These wheels will run quite a length of time without reoiling after the reservoir is once filled. While it costs something to equip mine cars with these patent axles, such an outlay will result in more economical operation, particularly if at the same time the very best quality of car oil obtainable is used.

**Lubricant Tests.**—There are certain simple tests that may readily be made to determine the suitability of certain oils for certain grades of work. When testing oils for use in connection with engines running under constant load and speed, Mr. W. W. Davis, of Boston, recommends that a thermometer be placed in the bearing so that the bulb rests on the shaft, a constant feed of oil being maintained. Another thermometer is hung in the engine room near the bearing and away from drafts of air, so as to show the temperature of the room. Commence the test when the engine is started, note the rise of

temperature at frequent intervals, also that of the room; continue the test until the temperature of the bearing ceases to rise. Every bearing will in the course of a few hours reach a point where heat is radiated as fast as generated. Deducting the temperature of the room from that of the bearing will give the rise in temperature due to friction. If the engine runs during the day only, the bearing will cool off over night and after cleaning thoroughly with gasoline, will be in condition to test another oil the next day.

While it is true that the coefficient of friction often decreases with the rise in temperature, in everyday practice it is safe to assume that of two oils the one that will keep the bearing the cooler is the best lubricant, so in tests of this kind the oil showing the least rise in temperature will be the better lubricant. Such tests can also be made in ring-oiled bearings of motors, dynamos, or shafting.

When testing the value of two or more cylinder oils, Mr. Ward recommends that one oil be fed in at a given rate for a few days, the cylinder head then removed, and the inner surface wiped over with a piece of soft white paper. If there is no stain of oil and a liberal amount has been used, either the steam is very wet or not enough fatty oil has been used in compounding the lubricant. A separator will remove the excess moisture from the steam, when further tests will indicate if there is enough fatty oil present.

The same tests can be used to determine the least amount necessary to maintain good lubrication. By gradually reducing the amount of oil fed and examining the surfaces from time to time the proper amount necessary to maintain good lubrication can be determined. Where tests of this kind are to be made some means must be provided for the easy removal of the cylinder heads.

## BEST LUBRICANTS FOR DIFFERENT PURPOSES (THURSTON)

| | |
|---|---|
| Low temperatures, as in rock drills driven by compressed air.................. | Light mineral lubricating oils. |
| Very great pressures and slow speed...... | Graphite, soapstone, and other solid lubricants. |
| Heavy pressures and slow speed......... | The solid mineral lubricants and lard, tallow, and other greases. |
| Heavy pressures and high speed......... | Sperm oil, castor oil, and heavy mineral oils. |
| Light pressures and high speed......... | Sperm, refined petroleum, olive, rape, cottonseed. |
| Ordinary machinery.................. | Lard oil, tallow oil, heavy mineral oils, and the heavier vegetable oils. |
| Steam cylinders...................... | Heavy mineral oils, lard, tallow. |
| Watches and other delicate mechanism. | Clarified sperm, neat's foot, porpoise, olive, and light mineral lubricating oils. |

For mixture with mineral oils, sperm is best; lard is much used; olive and cottonseed are good.

# STRENGTH OF MATERIALS

## DEFINITIONS

*Stress* is the cohesive force by which the particles of a body resist the external load that tends to produce an alteration in the form of the body. It is always equal to the effective external force acting upon the body; thus, a bar subjected to a direct pulling force of 1,000 lb. endures a stress of 1,000 lb.

*Unit stress* is the stress or load per unit of area, usually taken per square inch of section. For instance, if the bar just mentioned is 1 in. × 2 in. in section, the unit stress of the bar will be $1,000 \div 2$ (sectional area) = 500 lb.

*Tensile stress* is produced when the external forces tend to stretch a body, or pull the particles away from one another. A rope by which a weight is suspended is an example of a body subjected to tensile stress.

*Compressive stress* is produced when the forces tend to compress the body, or push the particles closer together. A post or column of a building is subjected to compresive stress.

## AVERAGE ULTIMATE STRENGTHS OF METALS, IN POUNDS PER SQUARE INCH

| Tin, cast............ | (6,000) | 3,500 | 1,800 | | 4,000 | 4,000,000 |
| Zinc, cast........... | (20,000) | 5,000 | 4,000 | | 7,000 | 13,000,000 |

NOTE.–Compression values enclosed in parentheses indicate loads producing 10% reduction in original lengths.

*Shearing stress* is produced when the forces tend to cause the particles in one section of a body to slide over those of the adjacent section. A steel plate acted on by the knives of a shear, and a beam carrying a load, are subjected to shearing stress.

Tension, compression, and shear are called *simple* or *direct stresses*, to distinguish them from bending and torsion.

The amount of alteration in form of a body produced by a stress is called *deformation*, or *strain*. It may be tensile deformation, compressive deformation, or shearing deformation, according as the stress producing it is tensile, compressive, or shearing. The *rate of deformation*, also called *unit deformation*, is the deformation of a body, subjected to tension or compression, per unit of

## AVERAGE ULTIMATE STRENGTHS OF WOODS, IN POUNDS PER SQUARE INCH

| Factor of safety | 10 | 10 | 5 | 5 | 4 | 6 | 2 | 4 | 4 |

length. If an iron bar 6 ft. long is subjected to a force that elongates it 1 in., the rate of deformation will be 1 in. ÷ 72 (length of the bar, in inches) = .0139 in.

The *modulus* or *coefficient of elasticity* is the ratio between the stresses and corresponding deformations for a given material, which may have a somewhat different modulus of elasticity for tension, compression, and shear. If *l* is the increase per unit of length of a material subjected to tensile stress, and *p* the unit stress producing this elongation, the modulus of elasticity

$$E = \frac{p}{l}$$

For example, a wrought-iron bar, 80 in. long, subjected to a unit tensile stress *p* of 10,000 lb., stretched .029 in. The unit strain *l*, or stretch per inch of length, is .029 in. ÷ 80 in. = .0003625 in. Then,

$$E = \frac{10,000}{.0003625} = 27,586,200 \text{ lb. per sq. in.}$$

The relation $E = p \div l$ is true only when equal additions of stress cause equal increases of strain. Previous to rupture, this condition ceases to exist, and the material is said to be strained beyond the *elastic limit*, which, therefore, is that degree of stress within which the modulus of elasticity is nearly constant and equal to the unit stress divided by the unit strain.

The *ultimate strength* of a given material in tension, compression, or shear is that unit stress which is just sufficient to break it, and is equal to the maximum stress causing rupture divided by the original area of the cross-section. The accompanying tables show the average ultimate strengths, in pounds per square inch, of both metals and woods.

*Working stress* is the maximum unit stress to which the parts of a structure are to be subjected.

*Factor of safety* is the ratio of ultimate strength to working stress. The factor of safety required for a structure depends on the material and on the character of the loads applied—that is, whether the loads are quiescent or such that cause impact and vibrations. For stone and brick, a factor of safety of from 10 to 30 is used; for timber, from 8 to 15; for cast iron, from 6 to 20; for reinforced concrete, from 4 to 6; and for structural steel, from 3 to 6.

It is obvious that structures subjected to loads causing impact should be designed for a higher factor of safety than those having to carry static loads. When a structure, as a bridge, carries both dead load and live loads, the modern practice favors the specifying of one working unit stress for both kinds of loads, and providing for the effect of vibration by increasing the live-load stress or bending moment by an amount $I$ determined from a so-called impact formula. The formula most in use for railroad bridges is

$$I = \frac{300}{L + 300} S$$

in which $S$ = maximum live-load stress or bending moment in member,
$L$ = length, in feet, of single track that must be loaded in order to obtain value $S$.

# SIMPLE, OR DIRECT, STRESS

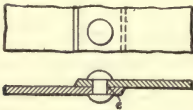
**Formula for Simple Stress.**—If $P$ is an external force producing tension, compression, or shear uniformly distributed over an area $A$, and $s$ is the unit working stress, the fundamental formula for designing parts of structures subjected to a simple, or direct, stress is

$$P = sA$$

When designing members that are in tension, $A$ must be taken as the net area of the section. This is determined by deducting from the gross section the greatest number of pin, bolt, or rivet holes that can be cut by a plane at right angles to the section. Rivet holes are usually taken $\frac{1}{8}$ in. larger than the diameter of the rivet.

**Important Applications of Formulas for Direct Stress.**—1. Tension members and short compression members of roof or bridge trusses are examples of simple stress, and their sections are determined by the preceding formula.

**EXAMPLE.**—A tension member of a roof truss is made of two $3\frac{1}{2}'' \times 3\frac{1}{2}'' \times \frac{1}{2}''$ angles connected by one line of rivets $\frac{7}{8}$ in. in diameter. What stress will it carry at 16,000 lb. per sq. in.?



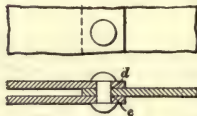


FIG. 1            FIG. 2

SOLUTION.—The gross sectional area of a $3\frac{1}{2}'' \times 3\frac{1}{2}'' \times \frac{1}{2}''$ angle is 3.25 sq. in. The deduction for one rivet hole is $(\frac{7}{8} + \frac{1}{8}) \times \frac{1}{2} = .5$. The net area is $3.25 - .5 = 2.75$. The carrying capacity of the angle is therefore $2.75 \times 16,000 = 44,000$ lb.

2. Riveted joints also are examples of simple stress. In the joint shown in Fig. 1, the rivet is in *single shear*, because there is only one section $e$ of the rivet subjected to a shearing stress. The amount $R$ that one rivet will carry being equal to the area of the cross-section of the rivet multiplied by the unit

## SHEARING AND BEARING VALUES OF RIVETS, IN POUNDS

| Diam. of Rivet Inch | Area of Rivet Square Inch | Shear Values at 6,000 Lb. per Sq. In. | | Bearing Values for Different Thicknesses of Plate, in Inches, at 12,000 Lb. per Sq. In. | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | Single Shear | Double Shear | 1/4 | 5/16 | 3/8 | 7/16 | 1/2 | 9/16 | 5/8 | 11/16 | 3/4 | 13/16 | 7/8 |

shearing stress, or $R = sA$, the number $n$ of rivets required to transfer a stress $T$ by single shear is

$$n = \frac{T}{R} = \frac{T}{As}$$

In Fig. 2, the rivet is subjected to shear on two sections, $d$ and $e$, and it is said to be in *double shear*. The amount of stress that one rivet can carry in double shear is twice that of one in single shear, and, using the preceding notation,

$$n = \frac{T}{2R}$$

The *bearing value* of a rivet is the compressive stress induced by the rivet in bearing on the plate, and is also calculated by the simple-stress formula

$$P = sA$$

in which

$P$ = value of rivet in bearing;
$s$ = unit working stress in bearing;
$A$ = bearing area.

It is customary to assume that the bearing area $A$ is the thickness of the plate multiplied by the diameter of the rivet. In calculating the required number of rivets, both the shearing and the bearing value of one rivet are determined and the critical value (the smaller) used.

The accompanying table gives the shearing and bearing values of rivets, in pounds, for different values of the working stress.

3. **Strength of Cylindrical Shells and Pipes With Thin Walls.**—When a cylinder is subjected to internal pressure, the tensile stress developed in the walls or shell of the cylinder is called *circumferential stress*, or *hoop tension*.

Let
$s$ = intensity of this stress;
$d$ = internal diameter of cylinder;
$p$ = intensity of pressure on inner surface of the cylinder;
$t$ = thickness of shell.

$$t = \frac{pd}{2s} \qquad s = \frac{pd}{2t}$$

The first formula serves to compute the thickness when $p$, $d$, and $s$ (working stress) are given; and the second one is used to compute the intensity of stress when the intensity of pressure $p$ and the dimensions of the cylinder are given.

EXAMPLE.—What should be the thickness of walls of a cast-iron water pipe, inside diameter 24 in., to resist a water pressure of 200 lb. per sq. in., using a unit working stress of 2,000 lb.?

SOLUTION.—Here, $d = 24$, $p = 200$, and $s = 2,000$. Substituting in the formula for $t$,

$$t = \frac{200 \times 24}{2 \times 2000} = 1.2 \text{ in.}$$

4. **Temperature Stresses.**—If a bar subjected to change of temperature is constrained so that it can neither expand nor contract, the constraint exerts on it a force sufficient to prevent the deformation. This causes in the bar a corresponding stress called *temperature stress*. It is compressive when the change of temperature is a rise, and tensile when a fall.

Let $T$ be the stress induced in a bar, whose area is $a$, by a rise or fall of $t°$; also let $c$ be the coefficient of expansion and $E$ the modulus of elasticity of the material. Then, $T = ctaE$

The coefficient of expansion for a number of substances is given in the section on Heat, Fuels, Etc.

EXAMPLE.—A wrought-iron bar 1.5 in. square has its ends fastened to firm supports. What is the stress produced in it by a change of 50° in its temperature?

SOLUTION.—Here, $E = 25,000,000$; $a = 1.5 \times 1.5 = 2.25$ sq. in., and $t = 50$; and, $c = .00000686$. Substituting in the formula, $T = .00000686 \times 50 \times 2.25 \times 25,000,000 = 19,294$ lb.

# BEAMS

A *beam* is a body resting upon supports and liable to transverse stress. Beams are designated by the number and location of the supports, and may be simple, cantilever, fixed, or continuous.

A *simple beam* is one that is supported at each end, the distance between its supports being the *span*.

A *cantilever* is a beam that has one or both ends overhanging the support; or a beam that has one end firmly fixed and the other end free.

A *fixed beam* is one that has both ends firmly secured.

A *continuous* beam is one which rests upon more than two supports.

**Reactions.**—The loads acting on a beam are balanced by the reactions or supporting forces; their sum must therefore be equal to the sum of the loads. To find any reaction, as $R_2$, at $B$, Fig. 1, take moments of all the external forces about the other support $A$ and divide their sum by the span. With reference to Fig. 1,

$$R_2 = \frac{W_1 a + W_2 b + W_3 c}{l}$$

The reaction $R_1$ can be found in a similar manner by taking moments about the support $B$. Their sum $R_1 + R_2$ must be equal to the sum of loads $W_1 + W_2 + W_3$.

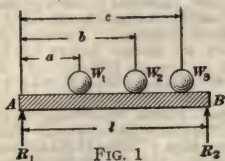

FIG. 1

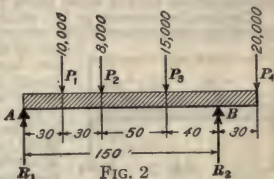

FIG. 2

EXAMPLE.—Find the reactions of a cantilever bridge loaded as shown in Fig. 2.

SOLUTION.—Substituting given values in the formula and noting that the moment of $P_4$ about $B$ is of opposite sign to the moments of the other loads,

$$R_1 = \frac{10,000 \times 120 + 8,000 \times 90 + 15,000 \times 40 - 20,000 \times 30}{150} = 12,800 \text{ lb.}$$

and

$$R_2 = \frac{10,000 \times 30 + 8,000 \times 60 + 15,000 \times 110 + 20,000 \times 180}{150} = 40,200 \text{ lb.}$$

The sum of the loads is $10,000 + 8,000 + 15,000 + 20,000 = 53,000$. The sum of the reactions is $40,200 + 12,800 = 53,000$.

**External Shear and Bending Moment.**—The forces acting on a beam tend, on the one hand, to shear its fibers vertically and, on the other hand, to bend it, producing compressional stresses in the fibers on one side of the neutral axis and tensional on the other side. The tendency to shear the fibers vertically is determined by the external shear, and that of bending by the bending moment. For brevity, external shear is often called simply *shear*, but it must not be confused with shearing stress at the section.

Forces acting upwards are considered positive, and those acting downwards, negative. The *external shear* at any section of a beam is the algebraic sum of all the external forces (loads and reactions) on one side of the section. It is equal to either reaction minus the sum of the loads between that reaction and the section considered. The maximum shear is always equal to the greater reaction. For a simple beam with a uniformly distributed load, the maximum shear is at the supports, and is equal to one-half the load, or to the reaction; the shear changes at every point of the loaded length, the minimum shear being zero at the center of the span. The maximum shear in a simple beam having a single load concentrated at the center is equal to one-half the load, and is uniform throughout the beam. Where a beam supports several concentrated loads, changes in the amount of shear occur only at the points where the loads are applied.

The external shear is resisted by the internal shear, or shearing stress, of the beam, which is numerically equal to the external shear. If the external shear is denoted by $V$, and the area of the cross-section by $A$, the average intensity of shearing stress in the section is $\frac{V}{A}$. This shearing stress is not uniformly distributed, and in beams of rectangular cross-section, the maximum intensity of shearing stress is $\frac{3V}{2A}$. Hence, a rectangular beam must be so designed that this value will not exceed the working shearing strength of the material.

In metallic beams with thin webs (plate girders), the shearing stress may be considered as uniformly distributed over the cross-section of the web. There is, also, at every horizontal or longitudinal section of the beam, a horizontal shearing stress the intensity of which at any point is equal to the intensity of the vertical shearing stress at that point.

Although the maximum intensity of shearing stress, both horizontal and vertical, in wooden beams is usually small, the shearing strength of wood along the grain is also small. As the horizontal external shear usually acts along the grain, the safe load for a wooden beam may depend on its shearing strength and not on its bending strength. For instance, the safe load for a beam 4 in. × 12 in. and 4 ft. long is 16,000 lb., uniformly distributed, when based on a fiber strength of 1,000 lb. per sq. in. Such a load will produce a shearing stress per unit of area equal to $\frac{3 \times 8,000}{2 \times 48} = 250$ lb. per sq. in., which exceeds the working shearing stress for the wood along the grain by about 100 lb. per sq. in.

The *bending moment* at any section of a loaded beam is equal to the algebraic sum of the moments of all the external forces (loads and reactions) to the right or

FIG. 3

left of the section about that section. For example, the bending moments at several points on the beam shown in Fig. 3 are as follows: At $W_1 = R_1a$; at $W_2 = R_1(a+b) - W_1b$; at $W_3 = R_1(a+b+c) - [W_2c + W_1(b+c)]$, or $R_2d$.

The bending moment varies, depending on the shear, and attains a maximum value at the point where the shear changes sign. If the loads are concentrated at several points, the maximum bending moment will be under the load at which the sum of all the loads between one support up to and including the load in question first becomes equal to, or greater than, the reaction at the support. Hence, to find the maximum bending moment in any simple beam:

**Rule.**—*Compute the reactions and determine the point where the shear changes sign. Calculate the moment about this point of either reaction, and of each load between the reaction and the point, and subtract the sum of the latter moments from the former.*

**EXAMPLE.**—What is the maximum bending moment of the beam loaded as shown in Fig. 4?

**SOLUTION.**—The reactions due to the uniform load are equal to one-half of the load; those due to the concentrated loads are computed by the principle given under Reactions. Both added give $R_1 = 18,170$ lb. and $R_2 = 14,330$ lb. Beginning at $R_1$ and sub-

FIG. 4

tracting the loads in succession, it is found that the shear just to the left of the load $d$ is $18,170 - 16,500$; and just to right of the load $d$ it becomes negative. Hence, the shear changes sign under the load $d$ and the bending moment is maximum at that point. It is equal to

$$18,170 \times 13 - 10,000 \times 7 - \frac{13^2 \times 500}{2} = 123,960 \text{ ft.-lb.}$$

Formulas for the maximum bending moments and shears for beams loaded and supported in different ways are given in the following table.

For a beam supporting moving loads, the maximum bending moment occurs:

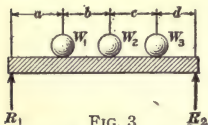
1. For a single load, when the load is at the middle of the span.

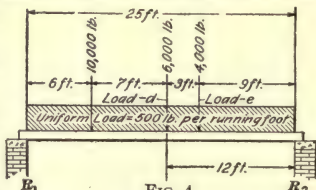
2. For two equal loads, under either load, when the two loads are on opposite sides of the center, and one of the loads is at a distance from the center equal to one-fourth the distance between the loads.

3. For two unequal loads, under the heavier load, when that load and the center of gravity of the two loads are equidistant from the center of gravity of the beam.

**EXAMPLE.**—A beam 24 ft. long supports two moving loads 6 ft. apart. The left-hand load is 8,000 lb., and the right-hand load is 4,000 lb. Find the maximum bending moment.

**SOLUTION.**—The center of gravity of the loads is 2 ft. from the left-hand load. The maximum bending moment occurs under the heavy load, and obtains when the latter is 1 ft. to the left of the center of the beam. The left reaction is, then, $\frac{12,000 \times 11}{24} = 5,500$ lb., and the maximum bending moment is $5,500 \times 11 = 60,500$ ft.-lb.

**Designing of Beams.**—In every section of a carrying beam there is induced an internal moment called the *moment of resistance*, which is equal to the bending




## FORMULAS FOR MAXIMUM SHEAR AND BENDING MOMENTS OF BEAMS

moment at that section. As previously explained, the resisting moment is equal to $\frac{I}{c}f$; and, if the maximum bending moment is denoted by $M$, $M = \frac{I}{c}f$; whence,

$$\frac{M}{f} = \frac{I}{c}$$

which is the fundamental formula for the designing of beams; $f$ is the working stress in flexure, which is the modulus of rupture divided by a suitable factor of safety.

The *modulus of rupture*, also called the *ultimate strength of flexure*, is the extreme fiber stress that a material subjected to bending can withstand. Its value is intermediate between the ultimate strength in compression and tension. The accompanying tables give the average values of the modulus of rupture for a number of materials.

When a beam is to be designed to carry certain loads, the maximum bending moment is determined and divided by $f$. The latter is usually given or is found by dividing the modulus of rupture of the material by a suitable factor of safety. The problem then reduces itself to the finding of a section that has a value of $\frac{I}{c}$, the section modulus, equal to $\frac{M}{f}$. For rolled-steel sections, the value of $\frac{I}{c}$ can be taken from a manufacturer's handbook. For a rectangular section,

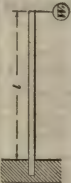
$$\frac{I}{c} = \frac{bd^2}{6}$$

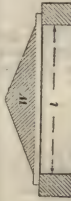
$b$ being the breadth and $d$ the depth of the section. As the expression contains two unknown quantities $b$ and $d$, a value for either one may be assumed and substituted, and the formula solved for the other. If a built-up beam is used the section has to be found by trial; a suitable section is first assumed and its section modulus is computed by the principles given under the heading Moment of Inertia; if necessary, it is modified until it is equal to $\frac{M}{f}$.

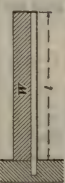
EXAMPLE.—Design both a rolled-steel **I** beam and a solid wooden beam 10 ft long, each to carry a uniform load of 250 lb. per ft. in addition to a central load of 2,000 lb., assuming for wood a working stress of 1,000 lb. per sq. in. and for steel 15,000 lb. per sq. in.

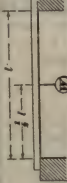
SOLUTION.—The maximum bending moment occurs at the middle of the beam and is equal to the sum of the moments due to the uniform load and the central load; therefore,

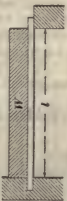
$$M = \frac{2,000 \times 120}{4} + \frac{250 \times 10 \times 120}{8} = 97,500 \text{ in.-lb.}$$

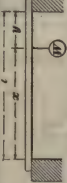
For a steel beam, $\frac{M}{f} = \frac{97,500}{15,000} = 6.5$. From a manufacturer's handbook, a 6-in. **I** beam of 12.25 lb. has a section modulus of 7.3 and can therefore be used. For a wooden beam, $\frac{M}{f} = \frac{97,500}{1,000} = 97.5 = \frac{bd^2}{6}$, assuming that $b = 6$ in., $d = \sqrt{97.5} = 10$ in. nearly.


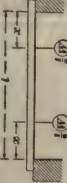


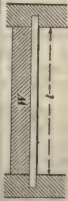


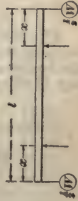












**Stiffness.**—When designing a beam, it is sometimes necessary to ascertain the amount that it will deflect under given loads. This, for instance, is the case when designing supports for machinery parts or joists for plastered ceilings, in which latter case the deflections should not exceed $\frac{1}{360}$ of the span. The following table gives deflection formulas for the most usual cases. In these formulas $l$ is the span, in inches; $W$, the total load acting on the beam; and $I$, the moment of inertia of the cross-section of the beam; and $E$, the modulus of elasticity of the material.

EXAMPLE 1.—A simple timber beam 10 ft. long, and having a width of 4 in. and a depth of 12 in., carries a uniform load of 400 lb. per ft. What is the deflection?

SOLUTION.—According to the table, the deflection for a uniformly distributed load is $\frac{5}{384}\frac{Wl^3}{EI}$. In this case, $l = 10 \times 12 = 120$; $W = 400 \times 10 = 4,000$; $E = 1,500,000$; and $I = \frac{4 \times 12^3}{12} = 576$. Substituting in the formula,

$$\text{Deflection} = \frac{5 \times 4,000 \times 120^3}{384 \times 1,500,000 \times 576} = .1 \text{ in.}$$

## FORMULAS FOR DEFLECTION OF BEAMS

## COLUMNS

The strength of a compression member depends on the ratio of its length to its least lateral dimension, or, what is the same thing, on the *ratio of slenderness;* that is, the ratio of its length to its radius of gyration.

For compression members whose ratio of slenderness does not exceed 30, the formula $s = \dfrac{P}{A}$, for simple stress, may be used.

When this ratio exceeds 30, but is not more than 150, $s$ should be deduced from *Rankine's formula,*

$$s = \frac{s_u}{1 + \dfrac{k_1 l^2}{r^2}}$$

in which
$\qquad s_u$ = ultimate strength in compression;
$\qquad l$ = length;
$\qquad r$ = radius of gyration.
$\qquad k_1$ = coefficient from table.

The ultimate strength in compression $s_u$ should be divided by a suitable factor of safety. Both $l$ and $r$ are expressed in the same unit. The values of $k_1$, which depend on the material of the column and the condition of its ends—that is whether fixed or round—are given in the following table:

### VALUES OF $k_1$ (RANKINE'S FORMULA)

| Material | Both Ends Flat or Fixed | One End Round | Both Ends Round |
|---|---|---|---|
| Cast iron..... | $\dfrac{1}{5,000}$ | $\dfrac{1.78}{5,000}$ | $\dfrac{4}{5,000}$ |
| Wrought iron. | $\dfrac{1}{36,000}$ | $\dfrac{1.78}{36,000}$ | $\dfrac{4}{36,000}$ |
| Steel......... | $\dfrac{1}{25,000}$ | $\dfrac{1.78}{25,000}$ | $\dfrac{4}{25,000}$ |
| Wood....... | $\dfrac{1}{3,000}$ | $\dfrac{1.78}{3,000}$ | $\dfrac{4}{3,000}$ |

When the value of $\dfrac{l}{r}$ exceeds 150, *Euler's formula,* which is given later, should be used.

The *straight line formula* is more convenient for determining the value of $s$, and is now in extensive use. It is only approximate, giving values of $s$ that differ somewhat from those obtained by Rankine's formula; but the difference is on the side of safety. For the same notation as before, the straight-line formula is
$$s = s_u - k \frac{l}{r}$$

### CONSTANTS FOR THE STRAIGHT-LINE AND EULER'S FORMULAS

| | Medium Steel | | Wrought Iron | | Cast Iron |
|---|---|---|---|---|---|
| | Flat Ends | Pin Ends | Flat Ends | Pin Ends | Flat Ends |
| $s_u$ ......... | 52,500 | 52,500 | 42,000 | 42,000 | 80,000 |
| $k$ ............ | 179 | 220 | 128 | 157 | 438 |
| limit of $\dfrac{l}{r}$ ...... | 195 | 159 | 218 | 178 | 122 |
| $nE\pi^2$ ........ | 666 m | 444 m | 666 m | 444 m | 395 m |

The values of $s_u$ and $k$ are given in the accompanying table, in which will also be found the limit of $\frac{l}{r}$ within which the formula may be used. When $\frac{l}{r}$ exceeds this limit, Euler's formula, which follows, should be used.

EXAMPLE.—What is the ultimate strength per square inch of a medium-steel column 25 ft. long both ends of which are fixed and the radius of gyration of which is 2.5?

## SAFE LOADS FOR HOLLOW, CYLINDRICAL, CAST-IRON COLUMNS
### (*The Carnegie Steel Co., Limited*)

| Outside Diameter Inches | Thickness of Metal Inches | Length of Columns in Feet | | | | | | | | | Sectional Area Inches | Weight of Columns per Foot of Length Pounds |

Solution.—By the straight-line formula,

$$s = 60,000 - 179 \times \frac{25 \times 12}{2.5} = 38,520 \text{ lb. per sq. in.}$$

Using Rankine's formula,

$$S = \frac{60,000}{1 + \frac{(25 \times 12)^2}{25,000 \times 2.5^2}} = 38,070 \text{ lb. per sq. in.}$$

**Euler's Formula.**—Structural members in compression whose ratio of slenderness exceeds 150 should preferably not be used. Sometimes, however, long columns cannot be avoided, and when $\frac{l}{r}$ exceeds the limits for which the preceding formulas may be applied, Euler's formula should be used. This formula is as follows:

$$\frac{P}{A} = \frac{n\pi^2 E}{\left(\frac{l}{r}\right)^2}$$

in which       $E$ = modulus of elasticity of material;

                $n$ = constant.

The value of the constant $n$ depends on the end condition; it has the value of 1 for columns with both ends pivoted and 4 for columns with both ends fixed. The table of constants on page 180 gives the values of $n\pi^2 E$, expressed in millions of pounds.

**Formula for Wooden Columns.**—The formula for determining the strength of wooden columns having flat or square ends was deduced from exhaustive tests of full-size specimens, made at the Watertown Arsenal, Mass., and may be expressed as follows:

$$S = U - \frac{Ul}{100d}$$

in which   $S$ = ultimate strength of column, per square inch of section;

           $U$ = ultimate compressive strength of material, per square inch;

           $l$ = length of column, in inches;

           $d$ = dimension of least side of column, in inches.

This formula may be applied to all wooden columns, the length or height of which is not under 10 times nor over 45 times the dimension of the least side. In other words, $\frac{l}{d}$ should not be less than 10 nor more than 45. If the length is less than 10 times the least side, the direct compressive strength of the material per square inch, multiplied by the sectional area of the column in square inches, will give the strength of the column. If the length is over 45 times the least side, Rankine's formula should be used.

---

# COMBINED STRESSES

**Bending Combined With Compression or Tension.**—Assume that $P$ is the axial force acting on the beam; $M$, the maximum bending moment to which the beam is subjected; $A$, the cross-sectional area of the beam; $I$, its moment of inertia; and $c$, the distance from the neutral axis of the most distant fiber, having the same kind of stress (tension or compression) as that caused by $P$. Then, the working stress should not exceed

$$s = \frac{P}{A} + \frac{Mc}{I}$$

In case of compression, $s$ should, in addition, be deduced from one of the compression formulas previously given.

The preceding formula for $s$ is the one commonly used in practice, but it is only approximate. When more accurate results are required, the following formula should be used,

$$s = \frac{P}{A} + \frac{Mc}{I \pm k\frac{Pl^2}{E}}$$

Here, $l$ is the span; $E$, the modulus of elasticity, and $k$, a constant having the following values:

*Value of k*

For a cantilever loaded at end.............................. $\frac{1}{8}$
For a cantilever loaded uniformly........................... $\frac{1}{4}$
For a beam supported at both ends and loaded at center..... $\frac{1}{12}$
For a beam supported at both ends and loaded uniformly...... $\frac{5}{48}$
For a beam fixed at both ends and loaded at center.......... $\frac{1}{16}$
For a fixed beam uniformly loaded.......................... $\frac{1}{32}$

The minus sign before $k$ is for the case when the direct stress is compressive, and the plus sign, when it is tensile.

## STRENGTH OF HEMP AND MANILA ROPES AND OF CHAINS

**Ropes.**—If $C$ is the circumference of a rope, in inches, and $P$ the working load, in pounds, then, for hemp and manila rope,

$$P = 10C^2$$

This formula gives a factor of safety of from $7\frac{1}{2}$ for manila or tarred hemp rope to about 11 for the best three-strand hemp rope.

For iron-wire rope of seven strands, nineteen wires to a strand,

$$P = 600C^2$$

and for the best steel-wire rope of seven strands, nineteen wires to the strand,

$$P = 1,000C^2$$

The last two formulas are based on a factor of safety of 6.

**Chains.**—If $P$ is the safe load, in pounds, and $d$ the diameter of link, in inches, then, for open-link chains made from a good quality of wrought iron,

$$P = 12,000d^2$$

and for stud-link chains, $P = 18,000d^2$

**Chain Cables.**—The strength of a chain link is less than twice that of a straight bar of a sectional area equal to that of one side of the link. A weld exists at one end and a bend at the other, each requiring at least one heat, which produces a decrease in the strength. The report of the committee of the U. S. Testing Board, on tests of wrought-iron and chain cables, contains the following conclusions:

"That, beyond doubt, when made of American bar iron, with cast-iron studs, the studded link is inferior in strength to the unstudded one.

"That when proper care is exercised in the selection of material, the strength of chain cables will vary by about 5% to 17% of the resistance of the strongest. Without this care the variation may rise to 25%.

"That with proper material and construction the ultimate resistance of the chain may be expected to vary from 155% to 170% of that of the bar used in making the links, and show an average of about 163%.

"That the proof test of a chain cable should be about 50% of the ultimate resistance of the weakest link."

From a great number of tests of bars and unfinished cables, the committee considered that the average ultimate resistance and proof tests of chain cables made of the bars, whose diameters are given, should be such as are shown in the accompanying table.

### ULTIMATE RESISTANCE AND PROOF TESTS OF CHAIN CABLES

| Diameter of Bar Inches | Average Resistance = 163% of Bar Pounds | Proof Test Pounds | Diameter of Bar Inches | Average Resistance = 163% of Bar Pounds | Proof Test Pounds |
|---|---|---|---|---|---|
| 1 | 71,172 | 33,840 | $1\frac{9}{16}$ | 162,283 | 77,159 |
| $1\frac{1}{16}$ | 79,544 | 37,820 | $1\frac{5}{8}$ | 174,475 | 82,956 |
| $1\frac{1}{8}$ | 88,445 | 42,053 | $1\frac{11}{16}$ | 187,075 | 88,947 |

| $1\frac{3}{8}$ | 128,129 | 60,920 | $1\frac{15}{16}$ | 241,463 | 114,806 |
| $1\frac{7}{16}$ | 139,103 | 66,138 | 2 | 256,040 | 121,737 |
| $1\frac{1}{2}$ | 150,485 | 71,550 | | | |

# PRACTICAL PROBLEMS IN THE STRENGTH OF BEAMS AND PROPS

**To Find the Quiescent Breaking Load of a Horizontal Square or Rectangular Beam Supported at Both Ends and Loaded at the Middle.**—Multiply the breadth, in inches, by the square of depth, in inches; divide the product by distance in feet, between supports, and multiply the quotient by the constant given in the Table of Constants for Seasoned Timber. Take as the safe working load one-third of the breaking load.

**To Find the Quiescent Breaking Load of a Horizontal Cylindrical Beam.** Divide the cube of the diameter, in inches, by the distance between the supports, in feet, and multiply the quotient by the constant.

When the load is uniformly distributed on the beam, the results obtained by the foregoing rules should be doubled.

EXAMPLE 1.—Find the quiescent breaking load and safe working load of a yellow-pine collar 8 in. square, 12 ft. between legs.

SOLUTION.—Breaking load $= \dfrac{8 \times 8^2}{12} \times 500 = 21,333$ lb. for seasoned, and 10,666 lb. for green timber.

Safe working load $= 7,111$ lb. for seasoned, and 3,556 lb. for green timber.

EXAMPLE 2.—Find the quiescent breaking load, and the safe working load of a hemlock collar 10 in. diameter, 7 ft. between legs.

SOLUTION.—Breaking load $= \dfrac{10^3}{7} \times 236 = 33,714$ lb. for seasoned timber, and $33,714 \div 2 = 16,857$ lb. for green timber.

Safe working load $= 33,714 \div 3 = 11,238$ lb. for seasoned, and $33,714 \div 6$ or $11,238 \div 2 = 5,619$ lb. for green timber.

**To Find the Load a Rectangular Collar Will Support When Its Depth Is Increased.**—When the length and width remain constant, the load varies as the square of the depth.

EXAMPLE.—A rectangular collar 10 in. deep supports 15,000 lb. What will it support if its depth is increased to 12 in.?

SOLUTION.—Applying the rule just given $10^2 : 12^2 = 15,000 : 21,600.$

**Having the Length and Diameter of a Collar, to Find the Diameter of a Longer Collar to Support the Same Weight.**—For the same load, the strength of collars varies as the cubes of their diameters, and inversely as their lengths.

EXAMPLE.—If a collar 6 ft. long and 8 in. diameter supports a certain weight, what must be the diameter of a collar 12 ft. long to support the same weight?

## TABLE OF CONSTANTS FOR SEASONED TIMBER

| Woods | Constant | | Woods | Constant | |
|---|---|---|---|---|---|
|  | Square or Rectangular | Round |  | Square or Rectangular | Round |
| Ash, white......... | 650 | 383 | Locust........... | 600 | 353 |
| Ash, swamp....... | 400 | 236 | Lignum vitæ..... | 650 | 383 |
| Ash, black........ | 300 | 177 | Larch........... | 400 | 236 |
| Balsam, Canada... | 350 | 206 | Maple........... | 550 | 324 |
| Beech, white...... | 450 | 265 | Oak, red or black | 550 | 324 |
| Beech, red........ | 550 | 324 | Oak, white....... | 600 | 353 |
| Birch, black...... | 450 | 265 | Oak, live......... | 600 | 353 |
| Birch, yellow...... | 450 | 266 | Pine, white....... | 450 | 265 |
| Cedar, white...... | 250 | 147 | Pine, yellow...... | 500 | 295 |
| Chestnut.......... | 450 | 265 | Pine, pitch....... | 550 | 324 |
| Elm............... | 350 | 206 | Poplar........... | 550 | 324 |
| Elm, rock......... | 600 | 353 | Spruce........... | 450 | 265 |
| Hemlock.......... | 400 | 236 | Sycamore........ | 500 | 295 |
| Hickory.......... | 650 | 383 | Willow.......... | 350 | 206 |
| Ironwood ........ | 600 | 353 |  |  |  |

SOLUTION.—Applying the rule just given $\sqrt[3]{12}:\sqrt[3]{6}\ =8$ in. : **6.35 in.**

**Having the Loads of Two Beams of Equal Length and the Diameter of One. to Find the Diameter of the Other.**—When the lengths are equal, the diameters vary as the cube roots of the loads, or the cubes of the diameters vary as the loads.

EXAMPLE 1.—A beam 11 in. in diameter supports a load of 32,160 lb. What will be the diameter of another beam the same length, to support a load of 19,440 lb.?

SOLUTION.—Applying the rule just given

$$\sqrt[3]{32,160}:\sqrt[3]{19,440}=11:9.3.$$

EXAMPLE 2.—A beam 8 in. in diameter will support a load of 10,240 lb. What load will a beam the same length and 7 in. in diameter support?

SOLUTION.—Applying the rule just given $8^3:7^3=10,240:6,860.$

The preceding Table of Constants has been calculated for seasoned timber; for green timber, take one-half of these constants. The safe working load is one-third of the breaking load.

**To Find the Diameter of a Collar When the Weight Increases in Proportion to the Length.**—Find the required diameter to support the same weight as the short collar. Then the length of the short collar is to the length of the long one as the diameter found to support the original weight is to the required diameter.

EXAMPLE.—If a collar 6 ft. long, 8 in. in diameter, supports a certain weight, what must be the diameter of a collar 12 ft. long to support twice the weight?

SOLUTION.—From the rule just given, $1:2=\dfrac{8^3}{6}:\dfrac{(\quad)^3}{12}$, or $1:2=2\times8^3:(\quad)^3$,

or $\sqrt[3]{1}:\sqrt[3]{2}::8\sqrt[3]{2}:12.7.$

**To Find the Breaking Load of Either Square or Rectangular Wooden Pillars or Props.**—Call one side of the square or the least side of the rectangle the breadth. Divide the square of the length, in inches, by the square of the breadth, in inches, multiply the quotient by .004, add 1 to the product and divide the crushing load by the result. Then multiply this quotient by the number of square inches in the end of the prop

Or, breaking load in lb. $=\dfrac{\text{Crushing load}}{\left(\dfrac{l^2}{b^2}\times.004\right)+1}\times bd,$

in which
$l=$ length, in inches;
$b=$ breadth, in inches;
$d=$ depth, in inches

## CRUSHING LOADS OF WELL-SEASONED AMERICAN WOODS

| Wood | Crushing Load Pounds per Square Inch | Wood | Crushing Load Pounds per Square Inch |
|---|---|---|---|
| Ash.................. | 6,800 | Maple, sugar, black.... | 8,000 |
| Beech................ | 7,000 | Maple, white, red...... | 6,800 |
| Birch................ | 8,000 | Oak, white, red, black.. | 7,000 |
| Cedar, red........... | 6,000 | Oak, scrub, basket..... | 6,000 |
| Cedar, white......... | 4,400 | Oak, chestnut, live..... | 7,500 |
| Chestnut............. | 5,300 | Oak, pin.............. | 6,500 |
| Hemlock............. | 5,300 | Pine, white........... | 5,400 |
| Hickory............. | 8,000 | Pine, pitch........... | 5,000 |
| Linden.............. | 5,000 | Pine, Georgia......... | 8,500 |
| Locust, black, yellow... | 9,800 | Poplar............... | 5,000 |
| Locust, honey........ | 7,000 | Spruce, black......... | 5,700 |
| Maple, broad-leafed, Oregon............. | 5,300 | Spruce, white......... | 4,500 |
|  |  | Willow............... | 4,400 |

For green timber, take one-half of the crushing strength given in the foregoing table. The safe working load equals one-third of crushing load.

| 30 | 3.36 |  | 4.34 |  | 6.40 | .11 | 7.97 |

Safe loads given include weight of beam. Maximum fiber stress 16,000 lb. per sq. in. For spacings below the heavy lines, the deflections will be greater than the allowable limit for plastered ceilings, equaling $\frac{1}{360}$ of span.

EXAMPLE.—What is the breaking load of a well-seasoned hemlock post 10 in. $\times$ 8 in. and 12 ft. long?

SOLUTION.—Applying the rule just given, $5,300 \div \left[1 + \left(\frac{144^2}{8^2} \times .004\right)\right]$ $= 2,308.4$ lb. per sq. in. of area. $2,308.4 \times 80 = 184,672$ lb. Ans.

**To Find the Breaking Load of a Cylindrical Wooden Prop.**—Find the breaking load of a square prop whose ends are equal in area to those of the cylindrical one, and proceed according to foregoing rule.

EXAMPLE.—What is the safe working load for a hemlock mine prop 10 in. diameter, 10 ft. long?

SOLUTION.—The area of the end of the prop $= 78.54$ sq. in. A square of equal area will have sides equal to $\sqrt{78.54} = 8.86 +$ in. Then,

$$5,300 \div \left[1 + \left(\frac{120^2}{8.86^2} \times .004\right)\right] = 3,058.3 \text{ lb. per each sq. in. of area.}$$

And $3,058.3 \times 78.54 = 240,198$ lb. This is the crushing strength of a similar prop of seasoned timber, but, as mine timber is used in its green state, take one-half of 240,198 lb., or 120,099 lb., as the crushing load of the prop in question. Then, the safe working load is one-third of this, or 40,033 lb.

The strength of similar props varies as the cubes of their diameters, and inversely as their lengths.

### IRON AND STEEL BEAMS

Constants for use in calculating the strength of iron and steel beams are: Cast iron, 2,000; wrought iron, 2,200; steel, 5,000. Hard steel will break the same as cast iron; soft steel will bend like wrought iron. The elastic limit of wrought iron is reached at about 2,200 lb. As it does not break, the limit of elasticity should be used.

**To Find the Quiescent Breaking Load of a Horizontal Square or Rectangular Iron or Steel Beam Supported at Both Ends and Loaded at the Middle.**—Multiply the square of its depth, in inches, by its breadth, in inches; multiply this result by the constant for the material used, and divide by the length, in feet, between the supports. For the net load, subtract one-half of the weight of the beam.

**To Find the Quiescent Breaking Load of a Cylindrical Iron or Steel Beam.** Find the breaking load of a square beam the sides of which are equal to the diameter of the round one, and multiply by .6.

The *safe working load* in each of the preceding cases is one-third of the breaking load. If the load is equally distributed over the beam, it will be twice as great.

# CONCRETE

## CEMENTING MATERIALS

### DEFINITIONS

Any substance that becomes plastic under certain treatment and subsequently reverts to a tenacious and inelastic condition may, in a broad sense, be termed a *cement*. However, nearly all the cementing materials employed in building construction are obtained by the heating, or *calcination*, as it is called, of minerals composed wholly or in part of lime. The different composition of these minerals, as well as the properties of the calcined products, enables the various resulting substances to be classified as *limes*, *hydraulic cements*, *plasters*, and *miscellaneous cements*. Although all these materials have cementing properties, the term *cement* is commonly used to apply only to the group made up of hydraulic cements, *hydraulic* meaning that these substances possess the ability to *set*, or become hard, under water.

Limes and hydraulic cements (commonly called simply *cements*) are composed essentially of oxide of calcium, or lime, generally called *quicklime*, with which may be combined certain argillaceous, or clayey, elements, notably silica and alumina, it being to these elements that the hydraulic properties of certain of these materials are due. The quantity of silica and alumina present in these substances enables them to be classified as *common limes*, *hydraulic limes*, and *cements*.

The ratio of the quantity of silica and alumina present in these materials to the quantity of lime is called the *hydraulic index*. In common limes, this index is less than $\frac{1}{100}$; in hydraulic limes, it lies between $\frac{1}{100}$ and $\frac{40}{100}$; and in cements, it exceeds $\frac{40}{100}$. These limes merge into one another so gradually, however, that it is often difficult to distinguish the dividing line between them.

## LIMES

The commercial varieties of lime may be classified as common, hydrated, and hydraulic. The common limes, also called quicklimes, may be subdivided into rich, or fat, lime and meager, or poor, lime.

**Common Limes.**—The grade of common lime known as *fat*, or *rich*, *lime* is almost pure oxide of calcium, $CaO$, and contains only about 5% of impurities. It has a specific gravity of about 2.3 and a great affinity for water, of which it absorbs about one-quarter of its weight. This absorption is accompanied by a great rise in temperature, by the lime bursting, and by the giving off of vapor. The lime finally crumbles into a powder. This powder occupies from two and one-half to three and one-half times as much volume as the original lime, the exact amount depending on its initial purity. When the lime is in this plastic state, it is said to be *slaked*. It is then unctuous and soft to the touch, and from this peculiarity it derives the name of *fat* or *rich*.

*Meager*, or *poor*, *lime* consists of from 60 to 90% of pure lime, the remainder being impurities, such as sand or other foreign matter. These impurities have no chemical action on the lime, but simply act as adulterants. Compared with fat lime, poor lime slakes more slowly and evolves less heat. The resulting paste is also thinner and not so smooth, greatly resembling fat slaked lime mixed with sand. Poor lime is not so good for building purposes as fat lime, nor has it such extensive use.

**Hydrated Lime.**—The class of lime called *hydrated lime* (calcium hydrate) is merely thoroughly slaked fat lime dried in the form of a fine powder, $Ca(OH)_2$. It is used extensively in conjunction with cement for making mortar, and also in the sand-lime brick industry.

**Hydraulic Limes.**—Limes that contain enough quicklime to slake when water is added, and enough clay or sand to form a chemical combination when wet, thus giving them the property of setting under water, are called *hydraulic limes*. The slaking qualities vary, the time of setting under water also varies, but these limes usually become as hard as stone in 3 or 4 da. The use of hydraulic lime has rapidly decreased in this country. Large quantities were formerly imported from Europe.

## CEMENTS

Cement may be divided into four general classes: Portland, natural, puzzolan (also called pozzuolana), and mixed. The relative importance of each cement is indicated by the order in which it is named.

*Portland cement* may be defined as the product resulting from the process of grinding an intimate mixture of calcareous (containing lime) and argillaceous (containing clay) materials, calcining (heating) the mixture until it starts to fuse, or melt, and grinding the resulting clinker to a fine powder. It must contain not less than 1.7 times as much lime by weight as it does of those materials that give the lime its hydraulic properties, and must contain no materials added after calcination, except small quantities of certain substances used to regulate the activity or the time of setting.

*Natural cement* is the product resulting from the burning and subsequent pulverization of an argillaceous limestone or other suitable rock in its natural condition, the heat of burning being insufficient to cause the material to start to melt.

*Puzzolan cement* is a material resulting from grinding together, without subsequent calcination, an intimate mixture of slaked lime and a puzzolanic substance, such as blast-furnace slag or volcanic scoria. That made from slag is know as *slag cement*.

*Mixed cements* cover a wide range of products obtained by mixing, or blending, the foregoing cements with one another or with other inert substances. *Sand cements*, *improved cements*, and many second-grade cements belong to this class. Mixed cements, however, are of comparatively little importance.

**Properties of Cements.**—The hydraulic cements differ from the limes in that they do not slake after calcination and that they set, or harden, under water. They can be formed into a paste with water without any sensible increase in volume and with little, if any, disengagement of heat. They do

not shrink appreciably in hardening, so that the sand and broken stone with which they are mixed are employed merely through motives of economy and not, as with limes, of necessity.

The color of the different grades of cement is variable, but in certain cases it is distinctive. Portland cement is a dark bluish or greenish gray; if it is a light yellow, it may indicate underburning. Natural cement ranges in color from a light straw, through the grays, to a chocolate brown. Slag cement is gray with usually a tinge of lilac. In general, however, the color of cement is no criterion of its quality.

Cement is packed either in wooden barrels or in cloth or paper bags, the latter being the form of package most commonly employed. A barrel of Portland or of slag cement contains the equivalent of 4 bags, while but 3 bags of natural cement equal a barrel. The average weights of the various cements are given in the accompanying table.

In proportioning mortar or concrete by volume, a common assumption is that a bag of Portland cement occupies .9 cu. ft. This practice, however, is, not entirely uniform.

### AVERAGE WEIGHTS OF HYDRAULIC CEMENTS

| Kind of Cement | Net Weight of Bag Pounds | Net Weight of Barrel Pounds | Weight per Cubic Foot Pounds | |
|---|---|---|---|---|
| | | | Packed | Loose |
| Portland........... | 94 | 376 | 100 to 120 | 70 to 90 |
| Natural........... | 94 | 282 | 75 to 95 | 45 to 65 |
| Slag.............. | $82\frac{1}{2}$ | 330 | 80 to 100 | 55 to 75 |

Portland cement may be distinguished by its dark color, heavy weight, slow rate of setting, and greater strength. Natural cement is characterized by lighter color, lighter weight, quicker set, and lower strength. Slag cement is somewhat similar to Portland, but may be distinguished from it by its lilac-bluish color, by its lighter weight, and by the greater fineness to which it is ground.

Portland cement is adaptable to any class of mortar or concrete construction, and is unquestionably the best material for all such purposes. Natural and slag cements, however, are cheaper, and, under certain conditions, may be substituted for the more expensive Portland cement. All heavy construction, especially if exposed, all reinforced-concrete work, sidewalks, concrete blocks, foundations of buildings, piers, walls, abutments, etc. should be made with Portland cement. In second-class work, as in rubble masonry, brick sewers, unimportant work in damp or wet situations, or in heavy work in which the working loads will not be applied until long after completion, natural cement may be employed to advantage. Slag cement is best adapted to heavy foundation work that is immersed in water or is at least continually damp. This kind of cement should never be exposed directly to dry air, nor should it be subjected either to attrition or impact.

### SAND AND ITS MIXTURES

*Sand* is an aggregation of loose grains of crystalline structure, derived from the disintegration of rocks. It is called *silicious, argillaceous,* or *calcareous,* according to the character of the rock from which it is derived. Sand is obtained from the seashore, from the banks and beds of rivers, and from land deposits.

The first class, called *sea sand,* contains alkaline salts that attract and retain moisture and cause efflorescence in brick masonry. This efflorescence is not at first apparent but becomes more marked as time goes on. It can be removed temporarily, at least, by washing the stonework in very dilute hydrochloric acid.

The second, termed *river sand,* is generally composed of rounded particles, and may or may not contain clay or other impurities.

The third, called *pit sand,* is usually composed of grains that are more angular; it often contains clay and organic matter. When washed and screened it is a good sand for general purposes.

Sand is used in making mortar because it prevents excessive shrinkage and reduces the quantity of lime or cement required. Lime adheres better to the particles of sand than it does to its own particles; hence, it is considered that sand adds strength to lime mortar. On cement mortar, on the contrary, sand has a weakening effect.

**Properties of Sand.**—The weight of sand is determined by merely filling a cubic-foot measure with dried sand and obtaining its weight. Dry sand weighs from 80 to 120 lb. per cu. ft.; moist sand, however, occupies more space and weighs less per cubic foot. The weight of sand is more or less dependent on its specific gravity and on the size and shape of the sand grains, but, other things being equal, the heaviest sand makes the best mortar.

The specific gravity of sand ranges from 2.55 to 2.80. For all practical purposes the specific gravity may be assumed to be 2.65 with little danger of error.

By *percentage of voids* is meant the amount of air space in the sand. Structurally, it is one of the most important properties of sand. The greater these voids, the more cement paste will be required to fill them in order to give a dense mortar. The percentage of voids may be determined by observing the quantity of water that can be introduced into a vessel filled with sand, but it is best computed as follows:

$$\text{percentage of voids} = 100 - \frac{100 \times \text{weight per cubic foot}}{62.5 \times \text{specific gravity}}$$

EXAMPLE.—What is the percentage of voids in a sand having a specific gravity of 2.65 and weighing 105 lb. per cu. ft.?

SOLUTION.—Substituting in the formula, the percentage of voids is

$$100 - \frac{100 \times 105}{62.5 \times 2.65} = 100 - 63.4 = 36.6$$

The percentage of voids depends principally on the size and shape of the sand grains and the gradation of its fineness, and hence will vary from 25 to 50%. Sand containing over 45% of voids should not be used to make mortars.

The *shape* of the grains of sand is of chief importance in the influence that the sand exerts on the percentage of voids. Obviously, a sand with rounded grains will compact into a more dense mass than one whose grains are angular or flat like particles of mica. Therefore, the more nearly the grains approach the spherical in shape, the more dense and strong will be the mortar for the same amount of cement. This fact is contrary to the common opinion on the subject.

The fineness of sand is determined by passing a dried sample through a series of sieves having 10, 20, 30, 40, 50, 74, 100, and 200 meshes, respectively, to the linear inch. The result of this test, expressed in the amount of sand passing each sieve, is known as the *granulometric composition* of the sand. Material that does not pass a ¼-in. screen is not considered to be sand, and should be separated by screening. Sand that is practically all retained on a No. 30 sieve is called *coarse*, while 80 or 90% of sand known as *fine* will pass through this sieve. Fine sand produces a weaker mortar than coarse sand, but a mixture of fine and coarse sand will surpass either one in those cases, at least, where there is not enough cement to fill voids using either sand.

The *purity*, or cleanness, of sand may be roughly ascertained by rubbing it between the fingers and observing how much dirt remains. To determine the percentage of the impurities more accurately, a small dried and weighed sample is placed in a vessel and stirred up with water. The sand is allowed to settle, the dirty water poured off, and the process repeated until the water pours off clear. The sand is then dried and weighed. The loss in weight gives the quantity of impurities contained in the sand. The presence of dirt, organic loam, mica, etc. is decidedly injurious and tends to weaken the resulting mortar. Clay or fine mineral matter in small proportions may actually result in increased strength, but excessive quantities of these materials may be a possible source of weakness. The best modern practice limits the quantity of impurities found by this washing test to 5%.

Attention is called to the fact that the sand found and used around many collieries is inferior. It is apt to be dirty and to consist of fine uniform grains. Such sand is sometimes suitable for building brattices or small foundations where a certain amount of air-tightness or weight, but not strength, is required. In all important work or in reinforced concrete, however, good, carefully selected sand should be used. The sand should always be tested to see whether it will make a mortar or a concrete of the desired qualities.

**Preparation of Sand.**—Sand is prepared for use by (1) screening to remove the pebbles and coarser grains, the fineness of the meshes of the screen depending on the kind of work in which the sand is to be used; (2) washing, to remove salt, clay, and other foreign matter; and (3) drying if necessary. When dry sand is required, it is obtained by evaporating the moisture either in a machine, called a *sand dryer*, or in large, shallow, iron pans supported on stones, with a wood fire placed underneath.

## LIME AND CEMENT MORTARS

*Mortars* are composed of lime or cement and sand mixed to the proper consistency with water. The proportions of the ingredients depend on the character of the work in which the mortar is to be used.

In proportioning mortar, the quantities of the separate ingredients are usually designated by a ratio, such as 1–1, 1–2, 1–3, etc. Thus, 1–2 signifies that 1 part of lime or cement is used to 2 parts of sand, etc. For great accuracy these measurements should be made by weight, but they are usually specified to be measured by volume.

**Lime Mortars.**—In lime mortar, besides effecting an economy, the presence of sand is necessary to prevent the shrinkage that would otherwise occur during the hardening of the paste.

When a mortar is made of lime and sand, enough lime should be present to just cover completely each grain of sand. An excess of lime over this quantity will cause the mortar to shrink excessively on drying, while a deficiency of lime will produce a weak and crumbly mortar. The correct quantity of lime depends on the character of the ingredients, the method of treatment and, to some extent on the judgment of the builder. The mixtures employed vary from 1–2½ to 1–5. Building laws in many municipalities require the use of a 1–3 mixture, and for most materials this proportion will be found satisfactory, although for rich, fat limes a 1–3½ or a 1–4 mixture is sometimes preferable.

In mixing lime mortar, a bed of sand is made in a mortar box, and the lime distributed as evenly as possible over it, first measuring both the lime and the sand in order that the proportions specified may be obtained. The lime is then slaked by pouring on water, after which it should be covered with a layer of sand, or, preferably, a tarpaulin, to retain the vapor given off while the lime is undergoing the chemical reaction of slaking. Additional sand is then used, if necessary, until the mortar attains the proper proportions.

Care should be taken to add just the proper quantity of water to slake the lime completely to a paste. If too much water is used, the mortar will never attain its proper strength, while if too little is used at first, and more is added during the process of slaking, the lime will have a tendency to chill, thereby injuring its setting and hardening properties. Rather than make up small batches, it is considered better practice to make lime mortar in large quantities and to keep it standing in bulk so that it can be used as needed.

Lime mortar is employed chiefly for brickwork of the second class, and its use is continually decreasing as that of cement increases. It is absolutely unsuitable for any important construction, because it possesses neither strength nor the property of resisting water. It cannot be used in damp or wet situations, nor should it ever be laid in cold weather, as it is very susceptible to the action of frost, being much injured thereby. Moreover, since it hardens by the action of dry air, only the exterior of lime mortar ever becomes fully hardened, so that anything like a concrete with lime as a matrix is impossible. However, for second-class brickwork, such as is commonly used in the walls of smaller buildings, lime mortars are economical and sufficiently good.

The strength of lime mortars is extremely variable, depending on the ingredients themselves and on their treatment, environment, etc. It is unsafe to figure a lime-mortar joint as possessing much strength, since only a part of the joint is hardened and capable of developing any strength at all. The tensile strength of thoroughly hardened 1–3 lime mortars averages from 40 to 70 lb. per sq. in., and the compressive strength from 150 to 300 lb.

**Cement Mortars.**—The sand for all mortars should be clean, of suitable size and granulometric composition. For structures designed to withstand heavy unit stresses, or for those intended to resist either the penetration of moisture or the actual pressure of water, the selection of the sand should be most carefully made. A simple method of determining the best sand for cement mortar is to prepare mixtures of the cement, sand, and water, using the same quantities in each case, and then to place each mixture in a measure; that mixture giving the least volume of mortar may be considered to contain the most desirable sand for use.

Limestone screenings, brick dust, crushed cinders, etc., are sometimes substituted for sand in making mortars, and, if care is taken in their selection, they may prove economical and entirely suitable for certain purposes.

The theory of the composition of a correctly proportioned mortar is that the cement paste will just a little more than fill all the voids between the particles of sand, thus giving an absolutely dense mortar at the least expense. The correct proportion of cement to sand, therefore, is more or less variable, depending on the granulometric composition of the sand. Since, however, Portland-cement paste that has set weighs nearly as much as sand, and since the average sand contains about 30 to 40% of voids, it is evident that 1–3 mixtures most nearly approach the best and most economical proportion.

Mortars, however, are made in proportions varying from 1–1 to 1–8. The richer mixtures are used for facing, pointing, waterproofing, granolithic mixtures, etc., the 1–2 mixture being usually made for such purposes. The leaner mixtures are used for rough work, filling, backing, etc., but should never be employed where either much strength or much density is desired. Natural-cement mortars are commonly made 1 part of sand less than Portland-cement mortars intended for the same purpose; that is, where a 1–3 Portland-cement mortar would be used, a 1–2 natural mortar would be required, although natural-cement mortars should be decreased by about 2 parts of sand to equal the strength of Portland. In other words, a 1–4 Portland mortar closely equals the strength of a 1–2 natural mortar. Puzzolan cements are usually proportioned the same as Portlands.

Cements are commonly proportioned by volume, the unit volume of the cement barrel being assumed. If a 1–3 mortar is desired, a box having a capacity of 10.8 cu. ft. is filled with sand and mixed with 4 bags or 1 bbl. of cement. A box 3 ft. $3\frac{7}{16}$ in. square and 1 ft. deep will have a capacity of very nearly 10.8 cu. ft. and, besides, makes a convenient size of box for actual work.

For general purposes, the mortar should be of a plastic consistency—firm enough to stand at a considerable angle yet soft enough to work easily. Wet mortars are easiest to work and are the strongest. However, they are subject to greater shrinkage, are slower setting, and are more easily attacked by frost. Dry mortars, on the other hand, are often friable and porous.

In the accompanying table are given the quantities of materials required to produce 1 cu. yd. of compacted mortar. The proportions are by volume, a cement barrel being assumed to contain 3.6 cu. ft. Of course, the exact values vary with the variety of sand, etc., but the table will serve as an approximation.

## MATERIALS REQUIRED PER CUBIC YARD OF MORTAR

| Kind of Mixture | Portland Cement Barrels | Loose Sand Cubic Yards |
|---|---|---|
| 1–1 | 4.95 | .65 |
| 1–2 | 3.28 | .88 |
| 1–3 | 2.42 | 1.01 |
| 1–4 | 1.99 | 1.06 |
| 1–5 | 1.62 | 1.11 |
| 1–6 | 1.34 | 1.15 |
| 1–7 | 1.18 | 1.17 |
| 1–8 | 1.05 | 1.18 |

EXAMPLE.—How much cement and sand will be required to obtain 8.5 cu. yd. of 1–3 Portland-cement mortar?

SOLUTION.—According to the table, 1 cu. yd. of a 1–3 Portland-cement mortar requires 2.42 bbl. of cement; therefore, 8.5 cu. yd. will require 8.5 × 2.42 = 20.57 bbl. of cement. Also, since 1 cu. yd. of a mixture of this kind requires 1.01 cu. yd. of sand, the quantity of sand required will be 8.5 × 1.01 = 8.59 cu. yd.

Mortar that is to be mixed by hand is prepared on a platform or in a mortar box. The sand is first measured by means of a bottomless box with handles on the sides. After filling the box, the sand is struck off level, the box lifted up, and the sand spread in a low, flat pile. The required number of bags of cement are then emptied on the sand and spread evenly over it. The pile is then mixed with shovels, working through it not less than four times. After

this operation, the dry mixture is formed into a ring, or crater, and the water intended to be used is poured into the center. The material from the sides of the basin is then shoveled into the center until the water is entirely absorbed, after which the pile is worked again with shovels and hoes until the mixture is uniform and in a plastic condition.

Another method of mixing, where a mortar box is used, is to gather the mixed dry materials at one end of the box and pour in the water at the other end, drawing the mixture into the water with a hoe, a little at a time, and hoeing until a plastic consistency is obtained.

**Properties and Uses of Cement Mortars.**—The strength of a mortar is measured by its resistance to tensile, compressive, cross-breaking, and shearing stresses, and also by determinations of its adhesion to inert surfaces, its resistance to impact, abrasion, etc. There is no definitely fixed ratio between the strength of mortar subjected to these different stresses, but there is nevertheless, a close relation between them, so that, practically, it may be assumed that if a mortar shows either abnormally high or low values in any one test, the same relation will develop when tested under other stresses. In practice, therefore, the strength of mortar is commonly determined through its resistance to tensile stresses, and its resistance to other forms of stress is computed from these results.

### TENSILE STRENGTH OF CEMENT MORTARS

| Proportions | | Age of Mortar | | | | | |
|---|---|---|---|---|---|---|---|
| | | 7 da. | 28 da. | 3 mo. | 7 da. | 28 da. | 3 mo. |
| Cement Parts | Sand Parts | Tensile Strength, in Pounds per Square Inch | | | | | |
| | | Portland Cement | | | Natural Cement | | |
| 1 | 1 | 450 | 600 | 610 | 160 | 245 | 280 |
| 1 | 2 | 280 | 380 | 395 | 115 | 175 | 215 |
| 1 | 3 | 170 | 245 | 280 | 85 | 130 | 165 |
| 1 | 4 | 125 | 180 | 220 | 60 | 100 | 135 |
| 1 | 5 | 80 | 140 | 175 | 40 | 75 | 110 |
| 1 | 6 | 50 | 115 | 145 | 25 | 60 | 90 |
| 1 | 7 | 30 | 95 | 120 | 15 | 50 | 75 |
| 1 | 8 | 20 | 70 | 100 | 10 | 45 | 65 |

The tensile strength of mortar has been shown to vary with the character of its ingredients, with its consistency, its age, and with many other factors. In the above table is given a fair average of the tensile strength that may be expected from mortars of Portland and natural cements that are made in the field and with a sand of fair quality but not especially prepared.

The strength of Portland-cement mortar increases up to about 3 mo.; after that period, it remains practically constant for an indefinite time. Natural-cement mortar, on the other hand, continues to increase in strength for 2 or 3 yr., its ultimate strength being about 25% in excess of that attained in 3 mo. The strength of slag-cement mortar averages about three-quarters of that of Portland-cement mortar.

The compressive strength of cement mortars is usually given in textbooks as being from eight to ten times the tensile strength. This value is rather high for the average mortar, a ratio of from 6 to 8 being one more nearly realized in practice. The ratio increases with the age and richness of the mortar, and varies considerably with the quality of the sand. Portland-cement mortars of 1–3 mixture that are 3 mo. old develop, on an average, a compressive strength of about 1,800 lb. per sq. in., while 1–2 natural-cement mortars average about 1,600 lb.

The strength of mortars in cross-breaking and shear may be taken at about one and one-half to two times the tensile strength, with a fair amount of accuracy.

The adhesion of mortars to inert materials varies both with the character of the mortar and with the roughness and porosity of the surfaces with which they are in contact. The adhesion of 1-2 Portland-cement mortar, 28 da. old, to sandstone averages about 100 lb. per sq. in.; to limestone, 75 lb.; to brick, 60 lb.; to glass, 50 lb.; and to iron or steel, 75 to 125 lb. Natural-cement mortars have nearly the same adhesive strength as those made of Portland cement.

In bricklaying and in other places in which mortar is employed it is frequently desired to use a material that is more plastic or smooth than pure cement mortar. This quality is usually obtained by adding from 10 to 25% of lime to the mortar. This addition of lime not only renders the mortar more plastic, and hence easier to work, but also increases both its adhesive strength and its density, which assists in making the mortar waterproof. Hydrated lime is to be preferred for use in cement mortar, because its complete slaking is assured. Hydrated lime may also be readily handled and measured on the work.

Occasionally, small quantities of cement are added to lime mortars so as to make them set quicker and to increase their strength. Such mixtures, however, are not especially economical nor are they convenient in practice.

**Retempering of Mortar.**—Mortar composed of cement, sand, and water soon begins to set and finally becomes hard. When it is desired to use this material, more water has to be added and the mixture worked until it again becomes plastic. This process is called *retempering*. Laboratory tests generally show that retempering slightly increases the strength of mortar, but the reworking is more thorough as a rule in the laboratory than would be the case in actual work. Any part of the hardened mortar that is not retempered is a source of weakness when incorporated in the building. The adhesive strength of cement, moreover, is greatly diminished by this process. For these reasons, it is generally inadvisable to permit the use of retempered mortars; but if they are allowed, great care should be taken to see that the second working is thorough and complete.

**Laying Mortar in Freezing Weather.**—Frost, or even cold, has a tendency to retard greatly the set of cement mortars. When the temperature, moreover, is so low that the water with which the mortar is mixed freezes before it combines with the cement, it may, if care is not exercised, result in complete destruction of the work. A single freezing is not particularly harmful, because when thawing occurs, the arrested chemical action continues. A succession of alternate freezings and thawings, however, is extremely injurious. Nevertheless, Portland-cement mortars may be laid even under the worst conditions if certain precautions are observed, but mortars of natural cement should never be used in extremely cold weather, as they are generally completely ruined by freezing.

The bad results that arise during mild frosts may be successfully guarded against by heating the sand and water and by using a quick-setting cement mixed rich and as dry as possible. In extremely cold weather, salt must be added to the water, so as to convert it into a brine that requires a temperature lower than 32° F. to freeze it. The common rule for adding salt is to use a quantity equal to 1% of the weight of the water for each degree of temperature that is expected below 32° F. Thus, at 32° F., a 1% solution would be used, while at 25°, an 8% solution would be required. Solutions greater than 12% should not be employed, and if a temperature below 20° F. is expected, heat must be used in addition to the salt. The finished work should also be protected with canvas or straw. Manure should not be used for this purpose, because the acids it contains tend to rot the cement. Unless the conditions are such as to make it imperative, it is not advisable to lay mortars during freezing weather.

**Shrinkage of Mortars.**—Cement mixtures exposed to the air shrink during the process of hardening, while those immersed in water tend to expand. The shrinkage of ordinary cement mortars is slight, and when they are used as a bonding material it need not be considered. When used as a monolith, as in sidewalks, shrinkage is guarded against by keeping the mortar wet during setting. This can be done by covering with moist straw or by sprinkling the mixture with water.

**Grouting.**—By grouting is meant the process of filling spaces in masonry with a thin, semifluid mixture known as *grout*. This mixture consists of cement, 1 or 2 parts of sand, and an excess of water. Grout can be used for filling the voids in walls of rubble masonry for backing arches and tunnels, for filling the joints between paving brick, and in all places where mortar cannot be laid in the ordinary manner. When hardened, grout is weak, friable, and porous.

# CEMENT TESTING

## FIELD INSPECTION AND SAMPLING

When *cement* is mentioned anywhere in the following pages, *Portland cement*, is meant, as this is by far the most important cement.

In order to determine correctly the structural value of a shipment of cement, an examination in the field is very necessary. A number of packages of cement should be weighed at intervals, and the average weight should never be permitted to fall below 94 lb. per bag, as mortar and concrete are usually proportioned on the assumption of this weight. Each package should also be plainly marked with the brand and name of the manufacturer; those not branded should be discarded, and, if possible, a mixture of different brands should be avoided.

A possible indication of inferiority is the presence of lumps throughout the bulk of the material. On standing, cement gradually absorbs moisture from the air. At first this moisture is present in merely a minute and harmless state, but eventually it combines chemically with the cement; that is, in the same manner as when cement and water are actually mixed together in practice. In the first condition, lumps usually appear, but they are so soft that they may be readily crushed with the fingers, and of course would be entirely broken up when mixed into mortar. When, however, the cement contains lumps that are hard and pebble-like and that can be crushed only with considerable effort, it indicates that chemical action has begun. Cement containing any appreciable amount of these hardened lumps is generally of decidedly inferior quality, and it should never be permitted to enter any important part of a structure.

Storing cement too long will tend to weaken it. Cement from 2 to 6 mo. old is usually the safest and will produce the best results.

The color of Portland cement, ranging from bluish to yellowish gray, affords no indication of quality except in cases where different shipments or different parts of the same shipment show a variation in color, thus pointing to a lack of uniformity.

**Sampling.**—When securing a sample for testing, the essential point is to get one that will fairly represent the entire shipment whose qualities are to be determined. The common practice is to take a small portion of material from every tenth barrel or, what is the same thing, from every fortieth bag. When tests are to be made, however, on a shipment of only a few barrels, more packages than one in ten should be opened; and when the shipment is large, say over 150 bbl., it should be subdivided and each portion tested separately. The bags selected should be taken at random and from different layers and not all from one part of the pile.

The cement, moreover, should be taken not only from the top of the packages, but from the center and sides as well. When the cement is contained in barrels, a sampling auger is used to extract the sample, a hole being bored in the staves midway between the heads. After the samples of cement have been taken from the packages they are thoroughly mixed in a can or basin, and this mixed sample is used for the various tests. To make a complete series of tests, the sample should contain from 6 to 8 lb. The cement, after sampling and before testing, must be well protected, as exposure to heat, cold, dampness, or any other abnormal condition may seriously affect the results.

**Purpose and Classification of Tests.**—In order that a mortar or a concrete made with cement shall give good results in actual construction, it must possess two important properties, namely, *strength* and *durability*. The primary purpose of cement testing, therefore, is to determine whether any particular shipment of cement possesses sufficient strength and durability to admit of its use in construction.

A determination of the quality of cement necessitates the employment of several tests, which may be classified as *primary tests* and *secondary tests*. The former tests, which include tests for *soundness* and tensile strength, are made to give directly a measure of the essential qualities of strength and durability. Unfortunately, neither of these tests is capable of being made with precision. Therefore, the secondary tests, which include tests to determine the time of setting, the fineness, the specific gravity, and the chemical analysis, are made to obtain additional information in regard to the character of the material. However, with the possible exception of the test of time of setting, the secondary tests have but little importance and only indicate by their results indirectly the properties of the material.

## PRIMARY TESTS

**Tests for Soundness.**—The property of cement that tends to withstand any forces that may operate to destroy or disintegrate it is known as *soundness*. This property, which is sometimes called *constancy of volume*, is the most important requisite of a good cement.

The most common cause of unsoundness in Portland cement is an excess of free or uncombined lime, which crystallizes with great increase of volume,

(a)        (b)        (c)

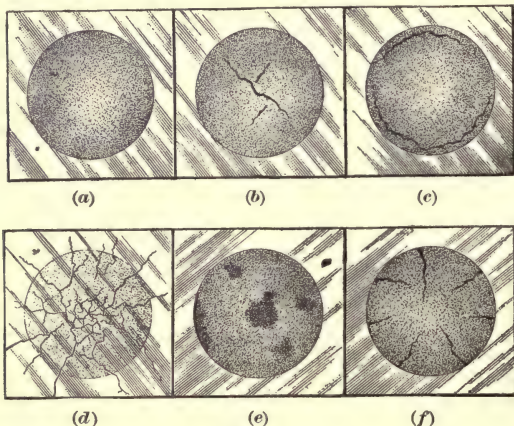
(d)        (e)        (f)


Fig. 1

and thus breaks and destroys the bond of the cement. This excess of lime may be due to incorrect proportioning or to insufficient grinding of the raw materials, to underburning, or to lack of sufficient storing before use, called *seasoning*. A certain amount of seasoning is usually necessary, because almost every cement, no matter how well proportioned or burned it may be, will contain a small amount of this excess of lime, which, on standing, will absorb moisture from the air, slake, and become inert.

Excess of magnesia or the alkalies may also cause unsoundness, but the ordinary cement rarely contains a sufficient amount of these ingredients to be harmful. Sulphate of lime is occasionally responsible for unsoundness, but this ingredient usually acts in the opposite direction, tending to make sound a cement that otherwise might disintegrate.

(a)

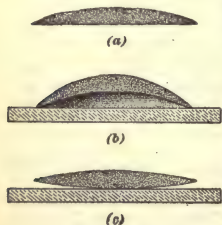
(b)

(c)

Fig. 2

The property of soundness is determined in one or more of three ways: by measurements of expansion, by normal tests, and by accelerated tests.

*Measurements of expansion* are made by forming specimens of cement, usually in the shape of prisms, and measuring the change in volume by means of a micrometer screw. At the present time, however, it is believed that expansion is not a sure index of unsoundness, so that this test is seldom employed.

*Normal tests* consist in making specimens of cement mixed with water, preserving them in air or in water under normal conditions, and observing their behavior. The common practice is to make on glass plates about 4 in. square, from a paste of neat or pure cement, two circular pats about 3 in. in diameter, $\frac{1}{2}$ in. thick at the center, and tapering to a thin edge. These pats are kept in moist air for 24 hr.; then one of them is placed in fresh water of ordinary temperature and the other


is preserved in air. The condition of the pats is observed 7 da. and 28 da. from the date of making, and thereafter at such times as may be desired.

The most characteristic forms of failure are illustrated in Figs. 1 and 2. Fig. 1 (a) shows a pat in good condition. View (b) illustrates shrinkage cracks that are due, not to inferior cement, but to the fact that the pat has been allowed to dry out too quickly after being made. Pats must be kept in a moist atmosphere while hardening, or these cracks, indicative merely of careless manipulation, will develop. View (c) shows cracks that are due to the expansion of the cement; this condition is common in the air pats, and is not indicative of injurious properties. Pats kept in water, however, should not show these cracks. View (d) shows cracking of the glass plate to which the pat is attached; this cracking is caused by expansion or contraction of the cement, combined with strong adhesion to the glass; it rarely indicates injurious properties. View (e) illustrates blotching of the pats, the cause of which should always be investigated by chemical analysis or otherwise, which may or may not warrant the rejection of the material. Slag cements or cements adulterated with slag invariably show this blotching. View (f) shows the radial cracks that mark the first stages of disintegration; such cracks should never occur with good material. They are signs of real failure, and cement showing them should never be used.

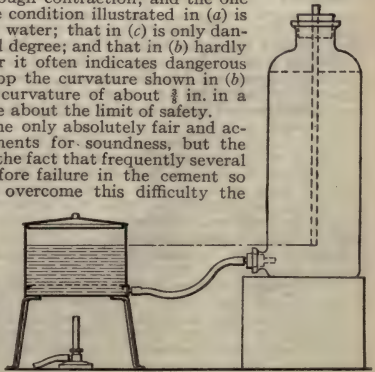
Fig. 2 shows three pats that, for different reasons, have left the glass plate on which they were made. The disk shown in (a) left the plate because of lack of adhesion; the one in (b), through contraction; and the one in (c), through expansion. The condition illustrated in (a) is never dangerous in either air or water; that in (c) is only dangerous when existing in a marked degree; and that in (b) hardly ever occurs in water, but in air it often indicates dangerous properties. Air pats that develop the curvature shown in (b) generally disintegrate later. A curvature of about $\frac{3}{8}$ in. in a 3-in. pat can be considered to be about the limit of safety.

The normal pat tests are the only absolutely fair and accurate methods of testing cements for soundness, but the serious objection to them lies in the fact that frequently several months or even years elapse before failure in the cement so tested becomes apparent. To overcome this difficulty the *accelerated tests* have been devised. These tests are intended to produce in a few hours results that require months in the normal tests.

Many forms of accelerated tests have been devised. At present, however, the only tests employed commercially are the boiling test and the steam test.

The *boiling test* is made by forming specimens of neat-

Fig. 3

cement paste into pats, such as are employed for the normal tests, or preferably into balls about $1\frac{1}{2}$ in. in diameter. The specimens are allowed to remain in moist air for 24 hr. and are then tested.


The form of the apparatus used for the boiling test is shown in Fig. 3. It consists of a copper tank that is heated by a Bunsen burner and is filled with water. The water in the tank is kept at a uniform height by means of a constant-level bottle. A wire screen placed an inch from the bottom of the tank prevents the specimens from coming into contact with the heated bottom. The test pieces, which are 24 hr. old, are placed in the apparatus, which is filled with water of a normal temperature, and heat is applied at a rate such that the water will come to boiling in about $\frac{1}{2}$ hr. Quiet boiling is continued for 3 hr., after which the specimens are removed and examined. Care must be taken that the water employed is clean and fresh, because impure water may seriously affect the results. The same water, also, should never be used for more than one test. A good cement will not be affected by this treatment, and the ball will remain firm and hard. Inferior cement will fail by checking, cracking, or entirely disintegrating.

The *steam test* is made in the same way as the boiling test, except that instead of immersing the specimens in water, they are kept in the steam above the water. The apparatus employed is the same as that used for the boiling

test.  The wire screen, however, is raised so that it is an inch above the surface of the water; also, there must be provided a cover that is close enough to retain the steam without creating pressure.  The steam test is less severe than the boiling test and is somewhat less accurate.

The result of the normal tests, if properly made and interpreted, may be considered reliable guides to the soundness of the material, and cement failing in these tests should always be rejected.  The accelerated tests, on the other hand, merely furnish indications, and are by no means infallible.  A cement passing the boiling test can generally be assumed sound and safe for use, but, if failure occurs, it simply means that other tests should be performed with greater care and watchfulness.  It often is advisable to hold for a few weeks cement that fails in boiling, so that the expansive elements may have an opportunity to hydrate and become inert; but if the material fulfils all the conditions except the boiling test, and is sound in the normal tests up to 28 da., it is generally safe for use.  All things being equal, however, a cement that will pass the boiling test is to be preferred.

**Tests for Tensile Strength.**—The tensile-strength test is for the purpose of ascertaining a measure of the ability of the material to withstand the loads that the structure must carry.  This test is made by forming specimens, called *briquets*, of cement and cement mortar, and determining the force necessary to rupture them in tension at the expiration of fixed intervals of time.  Cement constructions are rarely called on to withstand tensile stresses, but if the tensile strength is known, the resistance to other forms of stress may be computed with a fair degree of accuracy.  The tensile-strength test is the most convenient for laboratory determinations, on account of the small size of the specimens and the comparatively low stress required to cause rupture.

Cement is tested both neat or pure and in a mortar commonly composed of 1 part of cement and 3 parts of sand.  The periods at which the briquets are broken have been fixed by usage at 7 da. and 28 da. after making, although tests covering much longer periods of time are necessary in research or in investigative work.

The strength of cement and cement mortars varies considerably with the amount of water employed in making the briquets.  Dry mixtures ordinarily give the higher results for short-time tests, and wet mixtures show stronger with a greater lapse of time.  For testing purposes, therefore, it is essential that all cements be mixed, not with the same amount of water, but with the amount that will bring all the cements to the same physical condition, or to what is called *normal consistency*.  Different cements require different percentages of water because of their varying chemical composition, degree of burning, age, fineness, etc,

The normal consistency of neat-cement pastes may be determined by either of the methods that follow.  In these tests, the quantities are given in grams.

The first method is taken from that part of the final report of the Special Committee on Uniform Tests of Cement of the American Society of Civil Engineers which may be found on pp. 679 to 684, inclusive, of Vol. LXXV, Dec., 1912, of the Transactions of that Society.  In this method that quantity of cement that it is proposed to use subsequently in each batch for making test pieces should be weighed, but in no case should less than 500 grams be taken.  The amount is placed on a non-absorbent mixing slab in the form of a crater, and a definite amount of water poured into the center.  The cement is turned over from the sides into the center with a trowel until the water is absorbed.  It is then kneaded vigorously for 1 min. and quickly formed into a ball and tossed six times from one hand to the other maintained 6 in. apart.  During the operation of kneading and making the ball the hands should be protected by rubber gloves.  The ball of cement on the palm of the hand is then pressed into the large end of the hard-rubber ring of the Vicat apparatus in such a way that the ring is completely filled with paste.  A Vicat apparatus working on the same principle as the one illustrated in the Society's report and with the same weight of movable rod and the same principal dimensions is described in connection with Tests for Times of Setting.  The excess paste at the large end of the ring is removed with one movement of the palm of the hand, the ring is placed large end down on the plate under the movable rod, and the excess paste on the top is sliced off with a trowel held at an angle.  The paste must not be compressed.  The plunger is brought into contact with the surface of the material, quickly released, and its penetration noted.  The penetration should be exactly 10 millimeters in ½ min.; if the test shows a greater or less amount, other trials must be made, using more or less water, until the correct consistency is obtained.

The other method is to form of the paste a ball about 2 in. in diameter and to drop this ball on a table from a height of about 2 ft. If the cement is of the correct consistency, the ball will not crack nor will it flatten to less than one-half its original thickness. The percentage of water required will vary from 16 to 25, depending on the characteristics of the material, the average cement taking about 20%.

The consistency of sand mortars, however, cannot be obtained by either of the foregoing methods, because the sand grains do not permit of the measurement of the consistency by penetration, and the mixture is too incoherent for use of the ball method.

The accompanying table gives the amount of water required to make mortar of normal consistency and is given in the report of the committee just referred to above. It is for a mortar consisting of 1 part of cement and 3 parts of Standard Ottawa Sand. The amount of water is given as a percentage of the combined weight of the cement and sand. Each percentage corresponds with the water required for a normal consistency with the neat cement formed by the method recommended by the Committee.

### PERCENTAGE OF WATER FOR STANDARD SAND MORTAR

| Water in Neat Cement Per Cent. | Water in Standard Mortar Per Cent. | Water in Neat Cement Per Cent. | Water in Standard Mortar Per Cent. | Water in Neat Cement Per Cent. | Water in Standard Mortar Per Cent. |
|---|---|---|---|---|---|
| 15 | 8.0 | 23 | 9.3 | 31 | 10.7 |
| 16 | 8.2 | 24 | 9.5 | 32 | 10.8 |
| 17 | 8.3 | 25 | 9.7 | 33 | 11.0 |
| 18 | 8.5 | 26 | 9.8 | 34 | 11.2 |
| 19 | 8.7 | 27 | 10.0 | 35 | 11.3 |
| 20 | 8.8 | 28 | 10.2 | 36 | 11.5 |
| 21 | 9.0 | 29 | 10.3 | 37 | 11.7 |
| 22 | 9.2 | 30 | 10.5 | 38 | 11.8 |

The following formula has been devised to give the normal consistency to any mortar with any sand. It will be noted that the values derived by the formula differ somewhat from those given in the table.

Let $x$ = per cent. of water required for sand mixture;
$N$ = per cent. of water required to bring neat cement to normal consistency;
$n$ = parts of sand to one of cement;
$S$ = constant depending on character of sand.

Then,
$$x = \frac{3N + Sn + 1}{4(n+1)}$$

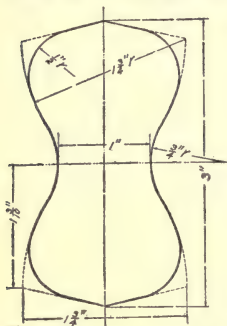
For crushed-quartz sand, the constant $S$ is 30; for Ottawa sand, it becomes 25; and for the bar and bank sands used in construction, it varies from 25 to 35, and must be determined for each particular sand.

EXAMPLE.—How much water is required in a mixture of 1 part of cement and 3 parts of crushed-quartz sand? The neat cement requires 19% of water to give normal consistency.

SOLUTION.—Here, $N = 19$, $S = 30$, and $n = 3$. Substituting these values in the formula,
$$x = \frac{3 \times 19 + 30 \times 3 + 1}{4 \times (3+1)} = 9.3\%$$

**Sand for Mortar Tests.**—The size, gradation, and shape of the particles of sand with which cement mortars are made have great influence on the resulting strength. There are two varieties of standard sand for cement testing, one an artificial sand of crushed quartz, the particles of which are angular in shape, and the other a natural sand from Ottawa, Illinois, the particles of which are almost spherical. Both sands are sifted to a size that will pass a sieve of 20 meshes to the inch and be retained on a sieve of 30 meshes, the diameters of the sieve wires being .0165 and .0112 in., respectively. The Ottawa sand will develop strengths in 1-3 mortars about 20 to 30% greater than those obtained with crushed quartz, and it is theoretically the better sand for testing. On most important works, tests for purposes of comparison are also made of the actual sand entering the construction.

**Briquets.**—The form of tensile briquet, adopted as standard in the United States, is shown in the accompanying figure; its cross-section is exactly 1 sq. in. These briquets are made in molds that come either single or in gangs of three, four, or five. The gang molds are preferable, as they tend to produce greater uniformity in the results. Molds should be made of brass or of some other non-corrodible material; those made of cast iron soon rust and become unfit for use.

When making the briquets, 1,000 g. of cement is carefully weighed and placed on the mixing table in the form of a crater, and into the center of this is poured the amount of water that is necessary to give the correct normal consistency. Cement from the sides of the crater is then turned into the center, by means of a trowel, until all the water is absorbed, after which the mass is vigorously worked with the hands, as dough is kneaded, for 1½ min. When sand mixtures are being tested, 250 g. of cement and 750 g. of sand are first weighed and thoroughly mixed dry until the color of the pile is uniform; then the water is added and the operation is completed by vigorous kneading.


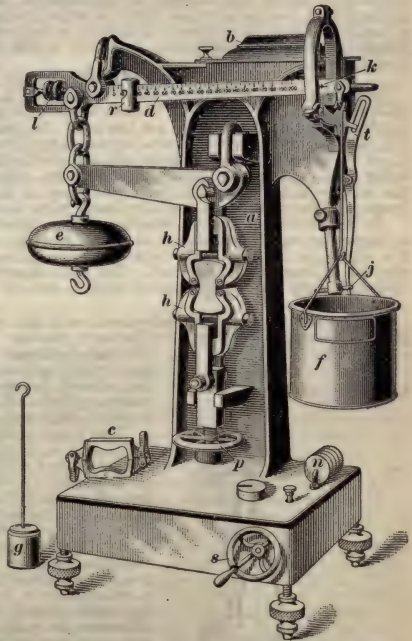
After kneading, the material is immediately placed into the molds, which should have been wiped with oil to prevent the cement from sticking to them. The entire mold is filled with material at once—not compacted in layers—and pressed in firmly with the fingers without any ramming or pounding. An excess of material is then placed on the mold and a trowel drawn over it under moderate pressure, at each stroke cutting off more and more of the excess material, until the surface of the briquets is smooth and even. The mold is then turned over, and more material placed in it and smoothed, as before. The mixing and molding should be performed on a surface of slate, glass, or some other smooth, non-absorbent material. During the mixing the operator should wear rubber gloves, so as to protect his hands from the action of the lime in the cement.

For 24 hr. after making, the briquets are stored in a damp closet so that the cement can harden in a moist atmosphere. The damp closet is simply a tight box of soapstone with doors of wood lined with zinc, or some similar arrangement, with a receptacle for water at the bottom and racks for holding the briquets. The briquets remain in the molds while in the damp closet, but at the expiration of 24 h, they are removed, marked, and placed in clean water near 70° F. until broken.

**Testing Machines.**—There are many styles of testing machines on the market; that shown is called a *shot machine* and is made by the Fairbanks Company. It is constructed on the cast-iron frame *a*, and is operated as follows: The cup *f* is hung on the end of the beam *d*, the poise *r* placed at the zero mark, and the beam balanced by turning the weight *l*. The hopper *b* is then filled with fine shot, and the briquet to be tested is placed in the clips *h*. The hand-wheel *p* is now tightened sufficiently to cause the graduated beam *d* to rise until the indicators at *k* are in line. In the case is a tension arrangement containing a worm and worm-gear that is connected to an axis that is threaded and passes up through the hand wheel *p* and into a block connected to the lower clip. A knob in the case engages this gear when it is required. After the hand-wheel *p* has been tightened until the indicators are in line, the worm is engaged and the automatic valve *j* is opened so as to allow the shot to run into the cup *f*. The flow of the shot can be regulated by means of a small valve located where the spout joins the reservoir. As the briquet stretches, the beam is kept stationary by applying tension to the briquet by means of the hand wheel *s*. When the briquet breaks, the beam *d* drops and by means of the lever *t* automatically closes the valve *j*. After the specimen has broken, the cup with its contents is removed, and the counterpoise *g* is hung in its place. The cup *f* is then hung on the hook under the large ball *e*, and the shot weighed. The weighing is done by using the poise *r* on the graduated beam *d* and the weights *n* on the counterpoise *g*. The result will show the number of pounds required to break the specimen. A mold for a single briquet is shown at *c*.

The load should be applied in all tests at the uniform rate of 600 lb. per min. The briquets should be broken as soon as they are removed from the storage tanks and while they are still wet, because drying out tends to lower their strength. The average of from three to five briquets should be taken as the result of a test.

Results of Tensile-Strength Tests.—The tensile strength of briquets tested in the preceding manner should increase with age up to about 3 mo., and should then remain practically stationary for longer periods. The average results of tests of Portland cement made in the Philadelphia laboratories, covering a period of several years and based on over 200,000 briquets, are given in the accompanying table.

Specifications for strength commonly stipulate minimum values for the 7- and 28-da. tests, the customary requirements for Portland cement being 500 lb. at 7 da. and 600 lb. at 28 da., when tested neat, and 170 lb. at 7 da. and 240 lb. at 28 da., when tested in a mortar consisting of 1 part of cement and 3 parts of crushed-quartz sand. When Ottawa sand is used, the requirements for mortar should be raised to 200 and 280 lb., respectively. Retrogression in strength in the periods specified is not often allowed. Although this retrogression in neat briquets between 7 and 28 da. is not necessarily indicative of undesirable


## TENSILE STRENGTH OF CEMENT BRIQUETS

| Mixture | 1 Hr. in Air 23 Hrs. in Water Pounds per Square Inch | 1 Da. in Air 6 Da. in Water Pounds per Square Inch | 1 Da. in Air 27 Da. in Water Pounds per Square Inch | 1 Da. in Air 89 Da. in Water Pounds per Square Inch |
|---|---|---|---|---|
| Neat........................ | 420 | 710 | 770 | 775 |
| 1 cement, 1 crushed-quartz sand............ | 360 | 590 | 695 | 700 |
| 1 cement, 2 crushed-quartz sand............ | 210 | 370 | 455 | 465 |
| 1 cement, 3 crushed-quartz sand............ | 105 | 210 | 300 | 310 |
| 1 cement, 4 crushed-quartz sand............ | 60 | 130 | 210 | 230 |
| 1 cement, 5 crushed-quartz sand............ | 35 | 80 | 155 | 195 |

properties according to some authorities, yet if the mortar briquets show retrogression, the cement should be condemned. Abnormally high strength in the 7-da. test of neat cement, say over 900 lb., may generally be taken as an indication of weakness rather than of superiority, because such a condition is usually created by an excess of lime or of sulphates, either of which may be injurious. Neat cement testing from 600 to 800 lb., at 7 da. is generally the most desirable.

## SECONDARY TESTS

**Tests for Time of Setting.**—The time-of-setting test is made to determine whether or not the cement will become hard at the time most desirable in actual construction. If it begins to set too soon, the crystallization of the particles will have begun before the mortar or concrete is thoroughly tamped into place. If, on the other hand, the cement sets too slowly the material is more likely to suffer from exposure to heat, cold, dampness, and frost; also, the progress of the work will be much delayed on account of the greater interval required between different sections, and the longer time the forms must be left up.

In the setting of cements, two stages are recognized: When the paste begins to harden or to offer resistance to change of form, called *initial set;* and when the setting is complete, or when the mass cannot be appreciably distorted without rupture, called *hard set.* The time-of-setting test consists, therefore, in determining the time required for the cement to reach these two critical points.

The test is made by mixing cement with the amount of water required to produce normal consistency, in the same manner as for neat tensile briquets,

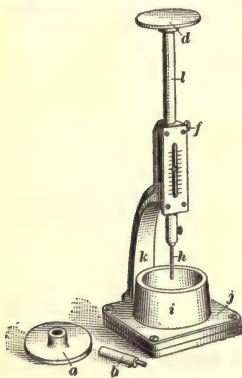
**FIG. 1**

forming specimens, placing them under one of the forms of apparatus, and observing the time that elapses between the moment the mixing water is added and the moments when the paste acquires initial set and hard set.

The *Vicat needle,* shown in Fig. 1, consists of a frame $k$, holding a movable rod $l$, which carries a cap $d$ at the upper end and a needle $h$ at the lower. A screw $f$ holds the rod in any desired place. The position of the needle is shown by a pointer moving over a graduated scale. The rod with needle and cap weighs exactly 300 g. and the needle is 1 mm. in diameter with the end cut off square. When making tests of normal consistency, the plunger $b$, which is 1 cm. in diameter, is substituted for the needle $h$, and the cap $a$ for the cap $d$, the difference in weight between the needle and plunger being compensated by the difference in the weight of the caps. The mold $i$ for holding the cement paste is in the form of a truncated cone. It has an upper diameter of 6 cm., a lower diameter of 7 cm., and a height of 4 cm., and rests on a $4'' \times 4'' \times \frac{1}{4}''$ glass plate $j$.

After the cement paste is mixed, the mold is filled by forcing the cement through the large end; then, after turning it over and smoothing the top, it is placed on the glass plate under the needle. The needle is lowered until it is exactly in contact with the surface of the paste, then quickly released and the depth to which it penetrates is read from the graduated scale. Initial set is said to have taken place when the needle ceases to penetrate to within 5 mm. of the bottom of the specimen; and hard set takes place when the same needle ceases to make an impression on the surface. Trials of penetration are made every 5 or 10 min. until these points are reached.

Time of setting varies considerably with the amount of mixing water employed, so that it is essential that every sample tested be brought exactly to normal consistency; otherwise, the results may be in decided error. Variations in temperature in both environment and in the mixing water, also influence the results. Standard practice requires that both the materials and the room in which the tests are made be at a temperature of as nearly 70° F. as practicable.

When specifying results to be obtained in testing the time of setting, it is obvious that a minimum value should be stipulated for initial set and a maximum, as well as a minimum, for hard set. It must also be remembered that a cement mixed with an aggregate and with an excess of water in the


field, will require from two to four times as long to set as the neat-cement paste mixed with little water in the laboratory. Cement, therefore, showing an initial set at the expiration of 20 min. with the Vicat needle, will rarely begin to set on the actual work in less than ¾ hr., which gives ample time for mixing and placing the materials, and cement setting in less than 10 hr., will usually have hardened completely in the work in 24 or at least in 36 hr. Specifications usually stipulate that Portland cement shall show initial set in not less than 20 minutes and shall develop hard set in not less than 1 hr. nor more than 10 hr. Cement reaching initial set in less than 12 or 15 min. should never be used for any work.

**Tests for Fineness.**—The fineness of cement is important, because it affects both the strength and the soundness of the product. The fineness of cement is determined by passing it through a series of sieves of different mesh and then measuring the amount retained on each. Three sieves are commonly employed, namely, those having 50, 100, and 200 wires to the linear inch. Sieves for cement testing should never be used until they have been carefully examined and found to conform to the following standard specifications:

1. Cloth for cement sieves shall be of woven brass wire of the following diameters: No. 50, .0090 in.; No. 100, .0045 in.; and No. 200, .00235 in.

2. Mesh to count on any part of the sieve as follows: No. 50, not less than 48 nor more than 50 per lin. in.; No. 100, not less than 96 nor more than 100 per lin. in.; and No. 200, not less than 188 nor more than 200 per lin. in.

3. Cloth to be mounted squarely and to show no irregularities of spacing.

The method of using the sieves in the fineness test is to weigh out 50 g. of cement on a scale sensible at least to $\frac{1}{20}$ g. and to place it on the No. 200 sieve, on which it is shaken until not more than $\frac{1}{20}$ g. passes the sieve at the end of 1 min. of shaking. The arrival of this stage of completion can be watched either by using a pan under the sieve or by shaking over a piece of paper. The residue remaining on the sieve is weighed, placed on the No. 100 sieve and the operation repeated, again weighing the residue. The amount remaining on the No. 50 sieve is then determined similarly. The process of sifting can be accelerated by placing a small quantity of coarse shot or pebbles on the sieves with the cement during the shaking. These may be separated from the cement by passing the residue with the shot through a coarse sieve, such as the No. 20.

Portland cement should be ground to such a fineness that it will leave a residue of not more than 25%, by weight, on the No. 200 sieve, and not more than 8% on the No. 100 sieve. Of these two requirements, the first is the more important, because it is only that part of the cement passing the finest sieve that is active in the setting and hardening of the material. The amount remaining on the No. 100 sieve is also important, because this part is most liable to cause unsoundness in the cement, and although specifications do not call for tests with the No. 50 sieve, it is usually employed for the same reason as the No. 100 sieve. Any appreciable residue on this sieve indicates that the material is much more liable to unsoundness. Any cement failing to pass the fineness test should be watched more carefully in the soundness and strength tests, but if these tests show good results up to 28 da., the cement can, as a rule, be used safely. It must be remembered, however, that only that part passing the No. 200 sieve is really cement, so that a coarsely ground shipment is practically equivalent to one adulterated with weak and unsound material.

**Tests for Specific Gravity.**—The object of the specific gravity test is to furnish indications of the degree of burning, the presence or absence of adulteration, and the amount of seasoning that the cement has received. When Portland cement is burned, the separate ingredients are in close contact and gradually combine by a process of diffusion. The greater the amount of this burning the more thoroughly are the elements combined. Thus, by their contraction they give, in volume, a higher density or specific gravity. Since, to secure good cement the burning must have been made within definite limits, it follows that the specific gravity must also lie within fixed limits if the cement has been properly manufactured.

The common adulterants of Portland cement, namely, limestone, natural cement, sand, slag, cinder, etc., all have specific gravities ranging from 2.6 to 2.75, while the specific gravity of Portland cement averages about 3.15. An appreciable amount of adulteration, therefore, is at once indicated in the results of the test.

Seasoning is indicated because the cement on standing gradually absorbs water and carbonic acid from the air. These ultimately combine with it and thus lower the specific gravity.

Of the many forms of apparatus employed for the specific-gravity test, the *Le Chatelier flask*, shown in Fig. 2, is the one most commonly used. It is also the one adopted by the technical societies as standard. It consists of a glass flask about 30 cm. high. The lower part up to mark *a* contains 120 cc., and the bulb between the marks *a* and *b* contains exactly 20 cc. The neck of the flask above the mark *b* is graduated into $\frac{1}{10}$ cc. The funnel *c* inserted in the neck is to facilitate the introduction of the cement.

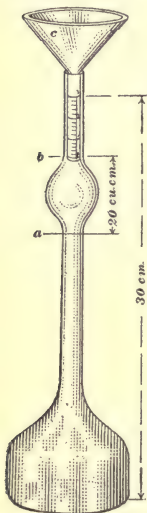


Fig. 2

The method of conducting the specific-gravity test is as follows: 64 g. of cement is carefully weighed on scales that should have a sensibility of at least .005 g. The flask is filled to the lower mark *a* with benzine or kerosene, which has no action on the cement, and is carefully adjusted precisely to the mark by adding the liquid a drop at a time. The funnel is then placed in the neck of the flask and the weighed cement introduced slowly through it, the last traces of the cement being brushed through with a camel's-hair brush. The funnel is then removed and the height of the benzine read from the graduations, estimating to .01 cc. The displaced volume is then 20 plus the reading, in cubic centimeters, and the specific gravity of the cement is 64 divided by that quantity. For example, suppose that the reading on the flask is .54, then the displaced volume will be $20 + .54 = 20.54$ and the specific gravity will be $64 \div 20.54 = 3.116$.

The apparatus must be protected from changes in temperature while in use; even touching the flask with the fingers will change the volume of the liquid noticeably. The flask is sometimes immersed in water during the tests to prevent these changes of temperature, but this precaution is unnecesary if proper care is exercised.

The specific gravity of well-burned Portland cement averages about 3.15 and should not fall below 3.1. If it falls below 3.1, tests should also be made on dried and on ignited samples to ascertain whether or not this condition has been produced by reason of excessive seasoning. As a rule, low specific gravity merely indicates well-seasoned cement, and if sound and sufficiently strong, such cement is the best sort of material for use, as its durability is scarcely open to question.

**Tests of Natural and Slag Cements.**—The methods of conducting tests of *natural* and *slag cements* are, in all important particulars, identical with those employed for Portland cement, although the results obtained and the interpretation to be put on them are often radically different. In the testing, the only essential difference is in the amount of water required by these cements to produce normal consistency; natural cement requires from 23 to 35% and slag cement takes about 18%, or an average of 2 or 3% less than Portland. Tests of natural cement for tensile strength are also frequently made on 1–1 and 1–2 mortars, but recent practice is to test mortars of all kinds of cement in 1–3 mixtures. For these cements, moreover, the specific-gravity test has practically no significance, except in determining the uniformity with which the different brands are made.

# CEMENT SPECIFICATIONS

A good example of a complete modern specification for Portland cement is here given.

## SPECIFICATIONS FOR PORTLAND CEMENT

**Kind.**—All cement shall be Portland of the best quality, dry and free from lumps. By Portland cement is meant the finely pulverized product resulting from the calcination to incipient fusion of an intimate mixture of properly proportioned argillaceous and calcareous materials to which no addition greater than 3% has been made subsequent to calcination.

**Packages.**—Cement shall be packed in strong cloth or canvas bags, or in sound barrels lined with paper, which shall be plainly marked with the brand

and the name of the manufacturer. Bags shall contain 94 lb. net and barrels shall contain 376 lb. net.

**Inspection.**—All cement must be inspected, and may be reinspected at any time. The contractor must submit the cement, and afford every facility for inspection and testing, at least 12 da. before desiring to use it. The chief engineer shall be notified at once on receipt of each shipment at the work. No cement will be inspected or allowed to be used unless delivered in suitable packages properly branded. Rejected cement must be immediately removed from the work.

**Protection.**—The cement must be protected in a suitable building having a wooden floor raised from the ground, or on a wooden platform properly protected with canvas. It shall be stored so that each shipment will be separate, and each lot shall be tagged with identifying number and date of receipt.

**Quality.**—The acceptance or rejection of a cement to be used will be based on the following requirements:

*Specific gravity:* Not less than 3.1.
*Ultimate tensile strength per square inch:* POUNDS
   7 da. (1 da. in air, 6 da. in water)........................... 500
  28 da. (1 da. in air, 27 da. in water)........................... 600
   7 da. (1 da. in air, 6 da. in water), 1 part cement to 3 parts of standard quartz sand.......................................... 170
  28 da. (1 da. in air, 27 da. in water), 1 part of cement to 3 parts of standard quartz sand.......................................... 240

*Fineness:* Residue on No. 100 sieve not over 8%, by weight; residue on No. 200 sieve not over 25%, by weight.

*Set:* It shall require at least 20 min. to develop initial set, and shall develop hard set in not less than 1 hr. nor more than 10 hr. These requirements may be modified where the conditions of use make it desirable.

*Constancy of Volume:* Pats of cement 3 in. in diameter, ½ in. thick at center, tapering to thin edge, immersed in water after 24 hr. in moist air, shall show no signs of cracking, distortion, or disintegration. Similar pats in air shall also remain sound and hard. The cement shall pass such accelerated tests as the chief engineer may determine.

*Analysis:* Sulphuric anhydride, $SO_3$, not more than 1.75%; magnesia, $MgO$, not more than 4%.

The common requirements for high-grade Portland, natural, and slag cements are given in the following table.

## REQUIREMENTS FOR HIGH-GRADE CEMENTS

| Requirements | Portland Cement | Natural Cement | Slag Cement |
|---|---|---|---|
| *Specific gravity:* | | | |
|   Not less than....................... | 3.1 | 2.8 | 2.7 |
| *Fineness:* | | | |
|   Residue on No. 100 sieve, not over..... | 8% | 10% | 3% |
|   Residue on No. 200 sieve, not over..... | 25% | 30% | 10% |
| *Time of Setting:* | | | |
|   Initial, not less than................. | 20 min. | 10 min. | 20 min. |
|   Hard, not less than................... | 1 hr. | 30 min. | 1 hr. |
|   Hard, not more than.................. | 10 hr. | 3 hr. | 10 hr. |
| *Tensile strength per sq. in.* | | | |
|   7 da., neat, not less than............. | 500 lb. | 125 lb. | 350 lb. |
|   28 da., neat, not less than............ | 600 lb. | 225 lb. | 450 lb. |
|   7 da., 1–3 quartz, not less than....... | 170 lb. | 50 lb. | 125 lb. |
|   28 da., 1–3 quartz, not less than...... | 240 lb. | 110 lb. | 200 lb. |
| *Soundness:* | | | |
|   Normal pats in air and water for 28 da. to be ........................... | sound and hard | sound and hard | sound and hard |
|   Boiling test to be ................. | sound and hard | | sound and hard |
| *Analysis:* | | | |
|   Magnesia, $MgO$, not over............ | 4% | | 4% |
|   Anhydrous sulphuric acid, $SO_3$, not over | 1.75% | | |
|   Sulphur, $S$, not over................. | | | 1.3% |

# PLAIN CONCRETE

## DEFINITIONS AND TERMS

*Concrete* is usually made of cement, sand, and broken stone. The cement in a plastic state, either by itself or with the sand that is generally mixed with it, is called the *matrix*, and the broken stone, gravel, or other material used as a filler is called the *aggregate*. The sand is correctly classed as a part of the aggregate, although some engineers mix it with the matrix. The aggregate is used to cheapen concrete. Pure, or neat, cement, when wet with water, would in a way fulfil all the physical requirements of concrete, but it would be too expensive.

In the concrete of today, hydraulic cement is used almost exclusively. For this reason, the term concrete, as commonly used, refers only to that variety. In specifying any other kind of concrete, the usual custom is to mention it by its full name, as *bituminous concrete, lime concrete*, etc. Such varieties, however, are of comparatively little importance.

The term concrete, besides being restricted to hydraulic-cement concrete, has another restriction: the aggregate must not be sand alone, although it may be partly sand. A mixture of hydraulic cement, sand, and water is called by the special name of *mortar*.

Concrete is usually named from the kind of aggregate used. For example, *stone concrete* embodies the use of broken stone or coarse pebbles, while in *cinder concrete*, the aggregate consists of cinders or broken slag.

The proportion of cement and sand to the broken stone depends on the spaces between the stones, which are known as *voids*. In all instances, there must be sufficient mortar to fill the voids entirely and to cover all surfaces of the separate stones.

## AGGREGATES OTHER THAN SAND

The aggregates or broken stone used in concrete work should possess three qualities: (1) They should be hard and strong, so as to resist crushing and shearing or transverse stresses; (2) they should have surface texture that will permit the cement mortar to adhere to their surfaces; and (3) where the concrete is to be used for building construction, such as in reinforced-concrete work, and for fireproofing, they should possess refractory, or fire-resisting, qualities. Usually, aggregates that break in such a way as to allow the smallest spaces, or interstices, between the particles, will make the strongest concrete for construction purposes because the voids can be most economically filled with cement mortar.

**Size of Aggregates.**—When measuring broken stone, the size of the stone is determined by the size of the ring through which it will pass. For instance, a 2-in. stone is one that will pass through a ring, or hole, that is 2 in. in diameter.

The broken stone used in concrete work varies in size with the nature of the work. For foundation and mass construction, it is the custom to use broken stone of a size that will pass through a 2- or 2½-in. ring. For filling the spandrels of bridges or the spaces between walls, where mere bulk is desired, broken stone of a much larger size is used.

In reinforced-concrete work, the broken stone must be small, owing to the narrow spaces in the forms. For columns and wall work, stone that will pass through a 1- or ¾-in. ring is suitable, while for filling beam and girder forms, where numerous reinforcing rods occur, the broken stone is sometimes so small as to pass through a ½-in. ring.

The latest practice in making concrete is to use stone as it comes from the crusher, without screening it. While such stone, termed the *run of crusher*, contains broken stone of a size specified, it also has smaller particles of stone and such stone dust as is carried along with the broken stone from the crusher. Where the run of crusher is used, the proportion of the cement and sand must be changed, because the stone dust takes the place of some of the sand. In using run of crusher the very finest dust should be washed or screened out as it tends to coat the large pieces and to prevent the cement from adhering to them.

The size of the aggregates has much to do with the quality and strength of the concrete. It can, however, be stated as a general proposition, that the larger the stones the stronger will be the concrete. This fact was well proved in a series of tests made at the Watertown Arsenal in 1898. These tests also showed that the concrete becomes heavier per cubic foot, or, in other words,

more dense, the larger the stone used. All these tests were made with concrete manufactured in the proportion of 1 part of cement, 1 part of sand, and 3 parts of broken stones, or a 1–1–3 (1 to 1 to 3) mixture, as it is usually expressed. The figures on cinder concrete (a 1 to 1 to 3) are added simply to give a comparison of weights, for it will be noted that the cinder concrete is older than the other concretes, and therefore stronger in proportion.

Aggregates that consist of stone of varying sizes are best for making concrete, owing to the fact that they pack closer. It is well, however, to screen all the fine particles, such as ½-in. sizes, and use them with the sand, as otherwise they will not mix properly with the cement.

**Selection of Aggregates.**—Usually the character of the aggregates used in mixing concrete depends on the availability of the supply. Where there is much choice in the selection of the aggregates those that are hardest and break with a cubical fracture will make the best concrete, although rounded pebbles are considered by some engineers to possess great advantages.

Some years ago the American Society of Civil Engineers, American Society for Testing Materials, American Railway Engineering and Maintenance of Way Association, and the Association of American Portland Cement Manufacturers appointed committees to obtain information concerning the practice in and properties of concrete and reinforced concrete and recommend formulas for design, etc. This general committee is commonly known as the Joint Committee and references will be made to its report in the following pages. These references are taken from the Proceedings of the American Society of Civil Engineers, Vol. XXXIX, No. 2, pp. 117 to 168, where the Progress Report of the Special Committee of that Society on concrete and reinforced concrete will be found. It was presented to that society by its committee on Jan. 15, 1913.

The relative merit of various aggregates for concrete cannot of course be defined accurately, because in any one aggregate the quality may vary considerably. The working stresses for concrete have been discussed by the Joint Committee. This committee recommends in its report certain tests for the ultimate strength of concrete. In the absence of such tests there are given certain values for the strength of concrete that should be obtained under certain conditions. The values given vary among other things with the kind of aggregate used. The aggregates are arranged into four groups in so far as they govern the strength of the concrete. These groups are as follows:

First group, granite, trap rock.
Second group, gravel, hard limestone, and hard sandstone.
Third group, soft limestone and sandstone.
Fourth group, cinders.

The difference in quality between any two adjacent groups is not constant. Elsewhere in the report it is stated: "Cinder concrete should not be used for reinforced-concrete structures. It may be allowable in mass for very light loads or for fire-protection purposes. The cinders should be composed of hard, clean, vitreous clinker, free from sulphides, unburned coal, or ashes."

## PROPORTIONING OF INGREDIENTS

**Effect on Strength and Imperviousness.**—The strength of concrete depends on the strength of the cement and the thoroughness with which the cement binds together the various pieces of aggregate. The more completely the voids are filled, the more completely will the aggregate be held together. Therefore, the more solid and condensed the concrete is, the less voids it will have, and the stronger it will be. The same is true with regard to making concrete water-proof; the more dense the concrete is, the more nearly water-proof it is.

A mixture of 1 part of cement, 1½ parts of sand, and 3 parts of stone, which would be considered extravagantly rich for a dry place, is probably as dense a concrete, and as good for waterproofing qualities, as can be made.

When a concrete is made of cement, sand, and stone, and the stone is of such a size that it will pass through a 3-in. ring, but will not pass through a 2½-in. ring, the concrete is weaker and requires more cement than one made with graded stone from 3-in. down. When the stone is graded in size, the stones of smaller size fill the voids between the larger stones and thus reduce the quantity of cement and sand required.

**Proportioning by Weights.**—The ingredients for a sample batch of concrete are weighed out in known proportions and mixed to the desired consistency on a sheet of steel. They are then tamped in a piece of 10-in. pipe capped at one end. The pipe thus partly filled is weighed, and subtracting the weight of the receptacle a check is obtained. The height of the concrete in the pipe is then

## COMPRESSIVE STRENGTH OF CONCRETE MADE OF DIFFERENT-SIZED STONES

| Material | First Group | | | Second Group | | | Third Group | | | Fourth Group | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|

| | | | | | | | 46 | 153.21 | | | | |

measured and the mixture dumped out before it hardens. After all the apparatus is cleaned another batch of concrete is mixed, using the same weight of water, cement, and total weight of sand and stone as before, but a different ratio of weight of sand to weight of stone. The height of this concrete in the pipe is measured. This operation is repeated. The concrete occupying the least volume is the densest and strongest that can be made with that particular sand and stone as they are and with the given proportion of cement. The volumes corresponding to the weights can be found by trial measurements.

**Usual Proportions of Materials.** — It is not always necessary to use the strongest concrete, as the concrete may be required to withstand only slight stresses and be simply used for its weight. The strongest concrete would then be unnecessarily expensive. Often the foregoing method of proportioning concrete is not employed and the engineer specifies a mixture from his own experience without testing the aggregates in any way, except to see that the stone is under the specified maximum size and properly graded, and that the sand is in large grains, graded down, and free from dirt and loam. A common proportion for unimportant work is 1–3–6. This proportion may be used for foundations below ground, in engine bases, in the foundations for asphalt pavements, and for similar purposes. A richer mixture 1–2–4 is used in piers, in dams, in important reinforced-concrete work, and in other places where great strength is desired.

In regard to the proportioning of ingredients the Joint Committee states as follows:

"*Quality and Proportions.*—The materials to be used in concrete should be carefully selected, of uniform quality, and proportioned with a view to securing as nearly as possible a maximum density.

"*Unit of Measure.*—The unit of measure should be the cubic foot. A bag of cement, containing 94 lb. net should be considered the equivalent of 1 cu. ft. The measurement of the fine and coarse aggregates should be by loose volume.

"*Relation of Fine and Coarse Aggregates.*—The fine and coarse aggregates should be used in such relative proportions as will insure maximum density. In unimportant work, it is sufficient to do this by individual judgment, using correspondingly higher proportions of cement; for important work these proportions should be carefully determined by density experiments, and the sizing of the fine and coarse aggregates should be uniformly maintained or the proportions changed to meet the varying sizes.

"*Relation of Cement and Aggregates.*—For reinforced-concrete construction, 1 part of cement to a total of 6 parts of fine and coarse aggregates measured separately should generally be used. For columns, richer mixtures are generally preferable; and in massive masonry or rubble concrete, a mixture of 1–9 or even 1–12 may be used.

"These proportions should be determined by the strength or the wearing qualities required in the construction at the critical period of its use. Experienced judgment based on individual observation and tests of similar conditions in similar localities is an excellent guide as to the proper proportions for any particular case.

"For all important construction, advance tests should be made of concrete composed of the materials in the proportions, and of the consistency to be used in the work. These tests should be made under laboratory conditions to obtain uniformity in mixing, proportioning, and storage, and in case the results do not conform to the requirements of the work, aggregates of a better quality should be chosen or richer proportions used to obtain the desired results."

**Water for Concrete.**—The wetter the concrete is, the easier it will be put in place, but mixtures that are too wet are not so strong as medium mixtures. The amount of water that will make the best mixture is such that after the concrete has been put in place and rammed it will quake like jelly when struck with a spade, and water will come to the surface. If the concrete is wetter than this, the water will have a slight chemical effect on the cement, and, moreover, the sand and cement will tend to separate from the broken stone.

In cinder concrete, owing to the porosity of the cinders, it is necessary to use a little more water, so that the cement will be liquid enough to fill the little cavities in each cinder. This precaution is indispensable when the concrete is to be used with steel, as otherwise the steel will be rapidly corroded by the action of air reaching it through the pores in the cinders.

## DESTRUCTIVE AGENCIES

Various causes may affect the strength and durability of concrete. The principal causes have been discussed by the Joint Committee already referred to, and as the various effects are often more or less complex it is probably best to quote directly from the Joint Committee.

"*Corrosion of Metal Reinforcement.*—Tests and experience indicate that steel sufficiently embedded in good concrete is well protected against corrosion, no matter whether located above or below water level. It is recommended that such protection be not less than 1 in. in thickness. If the concrete is porous, so as to be readily permeable by water, as when the concrete is laid with a very dry consistency, the metal may corrode on account of the presence of moisture and air.

"*Electrolysis.*—The most recent experimental data available on this subject seem to show that while reinforced-concrete structures may, under certain conditions, be injured by the flow of electric current in either direction between the reinforcing material and the concrete, such injury is generally to be expected only where voltages are considerably higher than those that usually occur in concrete structures in practice. If the iron is positive, trouble may manifest itself by corrosion of the iron accompanied by cracking of the concrete; if the iron is negative, there may be softening of the concrete near the surface of the iron, resulting in a destruction of the bond. The former, or anode effect, decreases much more rapidly than the voltage, and almost, if not quite,

disappears at voltages that are most likely to be encountered in practice. The cathode effect, on the other hand, takes place even at very low voltages, and is, therefore, more important from a practical standpoint than that of the anode.

"Structures containing salt or calcium chloride, even in very small quantities, are very much more susceptible to the effects of electric currents than normal concrete, both the anode and cathode effects progressing much more rapidly in the presence of chlorine.

"There is great weight of evidence to show that normal reinforced-concrete structures free from salt are in very little danger under most practical conditions, while non-reinforced-concrete structures are practically immune from electrolysis troubles. The results of experiments now in progress may yield more conclusive information on this subject.

"*Sea-Water.*—The data available concerning the effect of sea-water on concrete or reinforced concrete are limited and inconclusive. Sea walls out of the range of frost action have been standing for many years without apparent injury; in many harbors where the water is brackish, through rivers discharging into them, serious disintegration has taken place. This has occurred chiefly between low- and high-tide levels, and is due, evidently, in part to frost. Chemical action also appears to be indicated by the softening of the mortar. To effect the best resistance to sea-water, the concrete must be proportioned, mixed, and placed so as to prevent the penetration of sea-water into the mass or through the joints. The cement should be of such chemical composition as will best resist the action of sea-water; the aggregates should be carefully selected, graded, and proportioned with the cement so as to secure the maximum possible density; the concrete should be thoroughly mixed; the joints between old and new work should be made water-tight; and the concrete should be kept from exposure to sea-water until it is thoroughly hard and impervious.

"*Acids.*—Concrete of first-class quality, thoroughly hardened, is affected appreciably only by strong acids that seriously injure other materials. A substance like manure is injurious to green concrete, but after the concrete has hardened thoroughly it satisfactorily resists the action of such acid.

"*Oils.*—When concrete is properly made and the surface is carefully finished and hardened, it resists the action of such mineral oils as petroleum and ordinary engine oils. Oils that contain fatty acids produce injurious effects, forming compounds with the lime that result in a disintegration of the concrete in contact with them.

"*Alkalies.*—The action of alkalies on concrete is problematic. In the reclamation of arid land, where the soil is heavily charged with alkaline salts, it has been found that concrete, stone, brick, iron, and other materials are injured under certain conditions. It would seem that at the level of the ground water, in an extremely dry atmosphere, such structures are disintegrated through the rapid crystallization of the alkaline salts, resulting from the alternate wetting and drying of the surface. Such destructive action can be prevented by the use of a protective coating, and is minimized by securing a dense concrete."

**Effect of Fire on Concrete.**—Concrete is essentially a fire-proof material. All the ingredients of which it is composed are of a highly refractory nature, the aggregates being the elements of the mixture that are most quickly affected by intense heat. This is especially true of granite and limestone aggregates, the former being likely to crack or burst when heated, and the latter to calcine. After cement has set, the chemical union of its particles is liable to destruction by fire, because intense heat robs the cement of the water of crystallization, or *dehydrates* the cement, thus softening the material and making it crumbly. If concrete in a mass is subjected to intense heat, this action of dehydration extends into the concrete for a depth of only $\frac{1}{8}$ to $\frac{1}{2}$ in., and is not likely to penetrate farther.

**Effect of Mine Water on Concrete.**—The water from coal mines contains sulphuric acid, ammonium compounds, and other chemicals decidedly injurious to concrete. The use of concrete about the mines has assumed large proportions only in the last few years, and as yet no cheap method that is always effective has been uniformly adopted to protect the concrete from this water. Since the mine water will not attack silica, sand containing at least 92% silica should be used. The stone employed should also be acid-resisting and at least 90% insoluble in dilute hydrochloric acid. The cement should be properly burned and should be the best obtainable for such work. Some of the coal companies have special specifications for cement. Although the foregoing precautions will not make concrete entirely permanent in some conditions, they will increase its life.

**Expansion and Contraction.**—Considère, a French concrete expert, has found by experiment that a 1–3 mortar will shrink from about .05 to .15% when setting in air, and that the shrinkage will be two to three times as great with neat cement. The shrinkage in concrete will be much less than with neat cement or cement mortar.

The shrinkage of concrete is lessened by embedding in it steel rods or bars, as these, by their tensile resistance, prevent the shrinkage of the material when setting. By the experiments of Considère, it is found that with 1–3 mortar reinforced with steel the shrinkage when setting is about one-fifth that of the same mortar without the steel reinforcement.

**Effect of Thermal Changes on Concrete.**—Nearly all materials expand slightly as they become heated. Concrete and steel also follow this law. The contraction or the expansion of concrete due to changes in temperature is about the same as that of steel. The average coefficient of expansion of a 1–2–4 concrete for each Fahrenheit degree in change of temperature is .0000055. Experiments made on 1–3–6 concrete give a coefficient of expansion of .0000065, which is practically the same as the coefficient of steel.

**Effect of Vibration on Concrete.**—The effect of constant vibration on concrete structures has not been definitely determined. Many buildings and bridges constructed of concrete reinforced with steel rods and bars have withstood heavy and constant vibration, both continuous and intermittent, for an extended period of years with no apparent deterioration in strength. Fresh concrete is always, however, subject to deterioration by vibration, and the strength of concrete subjected to jar or shock when setting is materially reduced, because the process of crystallization between the particles, and the consequent cohesion of the mass, seems to be partly destroyed.

## WORKING STRESSES AND STRENGTH VALUES OF CONCRETE

The ultimate strength of concrete varies so with the proportion of the mixture, manner of working, character of ingredients, and age of material, that it is necessary to assume low unit working stresses for it.

There can be no unit stresses recommended for use for all conditions. It takes experience to make good concrete. Moreover, complete and detailed instructions and directions must be followed; more complete and detailed than there is room for here. The Joint Committee's report recommends for allowable stresses for concrete, certain percentages of the crushing strength of cylinders of the concrete, of certain size, and tested under certain conditions. In the absence of tests to learn this crushing strength, this report states that for cylinders of certain size, age, and method of manufacture, if made of 1–2–4, according to the directions laid down, of gravel, hard limestone, or hard sandstone, the crushing strength should be 2,000 pounds per square inch. The allowable stresses for such a concrete, when made of Portland cement, with static loads are:

|  | *Pounds per Square Inch* |
|---|---|
| *For Bearing* | |
| Axial compression, columns under 12 diameters | 450 |
| Compression in extreme fiber of beam, due to bending | 650 |
| Shear in beams, without web reinforcement | 40 |
| Shear, pounding shear | 120 |
| Bond, plain bars | 80 |
| Bond, drawn wire | 40 |

The strength of concrete varies, of course, with the age and richness of the mixture. To show this variation, the ultimate compressive strength of concrete of various ages and mixtures made from Portland cement, sand, and crushed stone, is given in the accompanying table. These results represent the product of some six hundred tests made by W. Purves Taylor, engineer-in-charge of the municipal testing laboratory of Philadelphia. Of course, to obtain similar figures, the concrete must be made and tested as it was in this experiment. The table, however, shows the increase of strength with age and richness of mixture.

## CONCRETE MIXTURES

**Methods of Measuring Ingredients.**—After deciding what proportions of ingredients will be used for the concrete, the engineer must be able to calculate the quantity of each material that he must order. An ordinary box car holds from 400 to 600 bags of cement. The purchaser is charged for the bags by the manufacturer, unless they are of paper, but he gets a rebate for those that are returned.

## AVERAGE ULTIMATE CRUSHING STRENGTH OF CONCRETE

| Proportion of Ingredients | | | Ultimate Crushing Strength Pounds per Square Inch | | | |
|---|---|---|---|---|---|---|
| Cement | Sand | Stone | 7 da. | 1 mo. | 3 mo. | 6 mo. |
| 1 | 2 0 | 4 | 1,600 | 2,150 | 2,400 | 2,500 |
| 1 | 2.5 | 5 | 1,430 | 1,950 | 2,250 | 2,350 |
| 1 | 3.0 | 6 | 1,250 | 1,800 | 2,100 | 2,200 |
| 1 | 3.5 | 7 | 1,100 | 1,660 | 1,960 | 2,080 |
| 1 | 4.0 | 8 | 980 | 1,520 | 1,820 | 1,950 |
| 1 | 4.5 | 9 | 850 | 1,400 | 1,690 | 1,840 |
| 1 | 5.0 | 10 | 750 | 1,260 | 1,550 | 1,720 |
| 1 | 5.5 | 11 | 650 | 1,120 | 1,420 | 1,600 |
| 1 | 6.0 | 12 | 600 | 1,000 | 1,300 | 1,500 |

Cement is usually measured by the barrel just as it comes from the manufacturer, or as 4 bags to the barrel, while broken stone and sand are measured loose in a barrel. Portland cement, after it is taken out of its original package and stirred up, fills a larger volume than when packed. It is therefore necessary to state just how the cement is to be measured; and, as said before, the custom is to measure it by the barrel, compact. A cement barrel contains about 3.8 cu. ft.

**Fuller's Rule for Quantities.**—A practical rule has been devised by W. B. Fuller whereby, after the proportions of ingredients have been fixed, the quantity of material for a certain work may be obtained with reasonable closeness. It is called *Fuller's rule for quantities*, and may be expressed in mathematical symbols as follows:

Let $c$ = number of parts of cement;

$s$ = number of parts of sand;

$g$ = number of parts of gravel or broken stone;

$C$ = number of barrels of Portland cement required for 1 cu. yd. of concrete;

$S$ = number of cubic yards of sand required for 1 cu. yd. of concrete;

$G$ = number of cubic yards of stone or gravel required for 1 cu. yd. of concrete.

Then
$$C = \frac{11}{c+s+g}, \quad S = \frac{3.8}{27} Cs, \text{ and } G = \frac{3.8}{27} Cg$$

If the broken stone is of uniformly large size, with no smaller stone in it, the voids will be greater than if the stone were graded. Therefore, 5% must be added to each value found by the preceding formulas.

EXAMPLE.—If a 1–2–4 mixture is considered, what will be: (a) the number of barrels of cement? (b) the number of cubic yards of sand? and (c) the number of cubic yards of stone required for 1 cu. yd. of concrete?

SOLUTION.—(a) Here $c = 1$, $s = 2$, and $g = 4$. Substituting these values in the first formula, $C = \frac{11}{1+2+4} = 1.57$.

(b) Substituting the values of $C$ and $s$ in the second formula, $S = \frac{3.8}{27} \times 1.57 \times 2 = .44$.

(c) Substituting the values of $C$ and $g$ in the third formula, $G = \frac{3.8}{27} \times 1.57 \times 4 = .88$.

## WORKING OF CONCRETE

**Mixing of Concrete.**—Concrete may be mixed either by hand or by machine. For small work, the concrete is mixed by hand in small batches, such as would be made up from 1 or 2 bags of cement. When mixing, hand work should be performed on a flat, water-tight platform. The sand, after it has been measured, is spread over the platform in an even layer. Upon the sand is placed the cement, and these two materials are turned over with shovels at least three

times, or until the uniform color of the mixture indicates that they are thoroughly incorporated. The stones, or aggregates, having previously been well wetted, are then placed on the top of the mixture of sand and cement, and these materials are also turned at least three times, water being added after the first turning. The water should always be added in small quantities. If a hose is used for this purpose, it should be fitted with a sprinkling nozzle, as otherwise much of the cement is liable to be washed out of the mixture. The concrete, when ready for placing, should be of uniform consistency, either mealy for a dry mix or mushy for a wet mix. In large work, the mixing should be done by machine.

**Retempering of Concrete.**—If the cement of the concrete has attained its initial set before being placed—that is, if the concrete has commenced to harden—remixing with water, or *retempering the concrete*, as it is called, should not be allowed; and if concrete treated in this manner has been deposited in the forms, it should be taken out and removed from the site of the operation, because concrete cannot be retempered properly, except in small quantities for laboratory tests.

**Concreting at High Temperatures.**—If the weather is extremely warm, the stone and sand are liable to become heated to a high temperature. In such cases, when the materials are being mixed, the water necessary for the crystallization of the cement is rapidly absorbed by the stone and the sand, or else is rapidly evaporated by contact with them. Besides, the extreme heat will hasten the setting of the cement, which gives it a tendency to cake in the mixing machine, producing lumpy and inferior concrete. In order to overcome such difficulties, the stone should be thoroughly wetted with a hose, and the sand and stone should be kept under cover, away from the direct rays of the sun. Likewise, the mixing platform or machine should be roofed over. It is well, also, to wet down the finished concrete work with a hose several times a day in extremely hot weather, and less frequently in moderate temperatures.

**Concreting in Freezing Weather.**—Although it is practicable to mix and place concrete at a temperature as low as 27° F., it is not advisable to lay concrete work when the temperature is below 32°; neither should it be mixed and placed even at this temperature, if there is a possibility that the temperature will fall. If concrete is frozen, its setting is retarded and it is liable to become worthless, never properly setting and obtaining the requisite hardness and strength. There is, however, no certainty of the action of frost on concrete, as frozen concrete will frequently thaw out and set, with apparently little loss of strength.

To prevent the freezing of concrete when the temperature has fallen below 32° F., salt is sometimes used in the mixture.

One rule is 1% of salt to the water for each degree below 32° F., as already stated in the case for mortar. More than 12% salt should never be used. The addition of salt, however, is never advisable if a surface finish is required, as the salt is liable to cause efflorescence, or a white deposit, on the surface causing the work to become very unsightly.

Aggregates that are coated with ice or that have been exposed to severe weather for a long time should be heated or thawed out before being used. Concrete that is exposed to freezing after it is set should always be protected by placing over it a layer of boards and straw, or salt hay, or cement bags; or, where the work is in the nature of a reinforced-concrete floor system, by heating the interior of the structure by means of salamanders or fires.

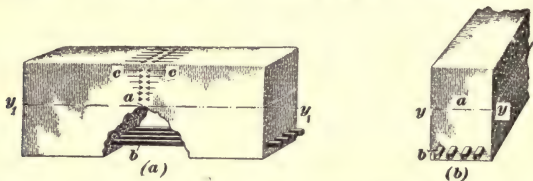
**Joining of Old Concrete With New.**—New and old concrete can be joined only with difficulty, and the strength of such a connection is always uncertain. The joining of old and new concrete work is best done by thoroughly chipping, or cutting away, the old surface, saturating it with water, and working into it thin coats of a 1–1 Portland-cement mortar, and, then, while the coating is still fresh, placing against it the new concrete.

There are some high-grade, imported cements that, in the form of cement mortar, more readily adhere to old concrete work than the usual Portland cements. These cements are frequently used for patching and piecing out work already in place.

# ELEMENTS OF STEEL REINFORCEMENT

## PRINCIPLES OF CONSTRUCTION

When a beam is subjected to tranverse stress, due to loads, the portion of the beam section above the *neutral axis*, or axis along which there is no stress, is in compression, while in that portion below the neutral axis, tensile stresses are created. Ordinarily, concrete is about ten times as strong in compression as it is in tension. Thus, it can readily be seen that a beam of plain concrete without steel reinforcement will fail primarily from lack of

(a)                              (b)


tensile resistance, without realizing its full compressive strength. In order, therefore, to make concrete an economical material to use in construction, its deficiency in tensile resistance must be made up by embedding steel rods, bars, or some other form of metallic reinforcement in that portion of the beam section subjected to tensile stress.

In order to explain more fully this primary principle of reinforced, concrete, reference is made to the reinforced, rectangular concrete beam here shown. The neutral line of the section is shown at $y_1 y_1$ in the side view (a), while the neutral axis is represented by $y y$ in the end view (b). When the concrete beam is under tranverse stress, there is neither tensile nor compressive stress at the neutral axis. Therefore, the point a in the beam which is on the neutral axis, is subjected to zero stress.

Should the concrete be cut away below the neutral plane, leaving the steel reinforcing rods, or bars, exposed at b, the strength of the beam will not be greatly affected, as the necessary tension below the neutral axis is supplied by the reinforcing rods of steel, while the necessary compression above it is furnished by the concrete, as at c. The amount of compression in each square inch of concrete above the neutral axis varies from zero at the axis to a maximum at the extreme upper surface of the beam. The concrete below the neutral axis $y y$ is usually so filled with very fine cracks that all the tension must be carried by the steel alone.

In ordinary reinforced-concrete column construction, merely vertical rods are employed. They are tied together, however, at intervals with wire or other ties.

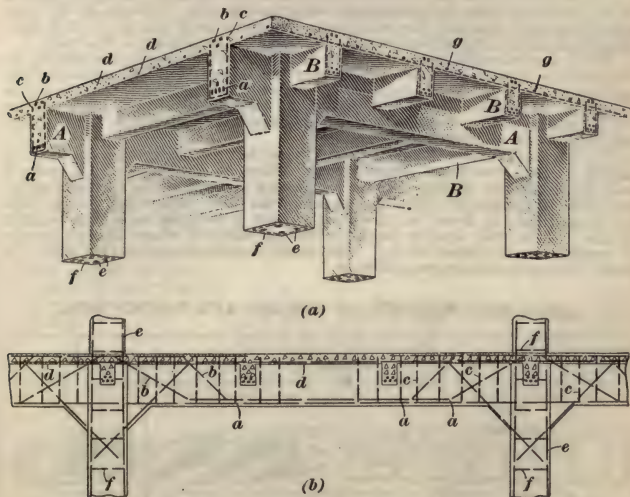
The principle of *hooped columns* is best explained as follows: It is well known that a column of sand will not resist compression, because it will spread, while a cylinder of very thin metal will sustain only a small load. However, if the cylinder is filled with sand, the tensile strength of the cylinder combined with the compressive resistance of the sand, will produce a column capable of resisting considerable compression. This principle is applied to the reinforcement of concrete columns by binding, or tying, together the concrete with cylindrical hoops, or helical, or spiral, windings of steel a few inches below the surface.

## PARTS OF STEEL REINFORCEMENT

In the accompanying illustration is shown a perspective view (a) of a complete bay of a reinforced-concrete floor system, and a diagrammatic representation (b) of a typical system of reinforcement for a concrete girder and column. In (a), the heavy members A running between columns are commonly known as *girders*, and the lighter members B running between girders, as *beams*. In both (a) and (b), the rods, or bars, a are the *main reinforcing bars*, or *rods*, of the girders. The beams, of course, have similar main reinforcing bars. Of these main reinforcing bars, several are bent up, as at b, to form *trussed bars*. The web reinforcement of the girders is shown at c, and consists of **U**-shaped pieces of iron or steel, called *stirrups*. The rods that

reinforce the slab of the reinforced-concrete floor system, called *slab rods*, are shown at *d*. This slab reinforcement may consist of straight rods, expanded

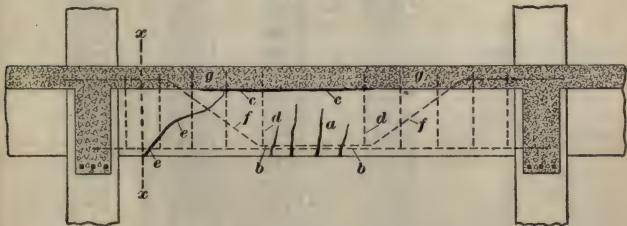
*(a)*

*(b)*


metal, woven-wire lath, or any other metallic reinforcement. The stirrups are bent over at the upper ends or fastened to the slab rods so that they will not pull out. The rods of the columns *e* are called *longitudinal column rods*, and the ties *f, column ties*.

Any rod, or bar, used to resist shearing stresses is designated as a *shear bar*. A rod, or bar, used to resist the shrinkage of the concrete in setting, or to provide against cracks due to thermal changes, is called a *shrinkage rod*. Shrinkage rods are shown at *g* in view (*a*). Sometimes all the slab rods run one way and an occasional shrinkage bar is used at right angles to them as shown, to prevent shrinkage cracks. A rod used to connect abutting beams or girders is called a *tension bar* or a *tie bar*. The short rods used at the splice when longitudinal column rods are butted are called *splice rods*, or *bars*.

**Members to Resist Lines of Failure.**—In the accompanying figure are illustrated a typical beam having the usual type of steel reinforcement and



the several methods of failure that might occur. At *a* are shown cracks, or lines of failure, that would be caused by lack of tensile resistance in the main reinforcing rods *b*. These cracks, are usually invisible, and generally extend

from the bottom surface to the neutral axis. They are nearly always present in concrete, but, of course, so long as the steel holds in, the beam will not fail.

If the main reinforcing rods do not extend to the bearings, failure by vertical shear may occur near the abutments, along the line $x\,x$. Failures of this kind seldom happen, because the main rods usually extend across all such lines of vertical shear, and add greatly to the shearing resistance of the beam.

If the slab concrete is not placed at the same time that the concrete of the beam section is poured, failure by shearing usually occurs at the junction of the beam with the slab, as shown at $c$. The shearing resistance at this junction should be increased, however, by extending stirrups $d$ into the slab. If the crack $c$ opens, it usually joins with a crack, like $e$, at each end of the beam, as suggested in the preceding paragraph.

The lines of failure indicated at $e$ are those that usually occur from diagonal tension stresses that cross these lines of failure at right angles. A beam is held against failure in this manner by placing stirrups in the concrete either vertically or obliquely. The bending up of the main reinforcing rods to form the trussed bar, as shown at $ff$, will also assist in resisting such stresses, and, besides, will provide against negative bending moment where tension instead of compression is created at $gg$. The line of fracture shown at $ee$ is typical of nearly all reinforced-concrete failures.

## AREAS AND WEIGHTS OF SQUARE AND ROUND BARS

| Size Inches | Square ■ | | Round ● | |
|---|---|---|---|---|

## REINFORCING MATERIALS

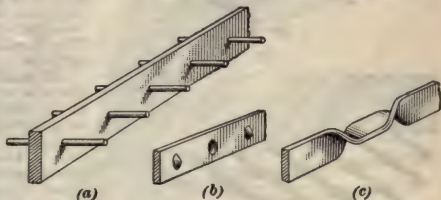
The reinforcement for concrete is almost uniformly steel, but the grade to be used should be determined by one who has made a careful study of this matter. He should both write the specifications and inspect the steel afterwards to make sure that the steel specified has been furnished. Steel used for reinforcement should be free from rust and scale or any coating that will tend to weaken the bond between the metal and the concrete.

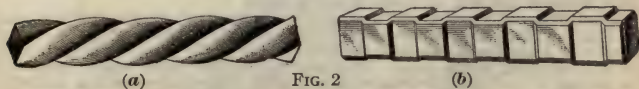
**Plain Bar Iron.** The cheapest form of metallic reinforcement for concrete is the *plain, round, rolled bar.* This bar can be obtained in any part of the United States and as its price per pound is lower than

FIG. 1

that of any other form of rolled steel, it is the cheapest and most available material. For slabs, $\frac{3}{8}$- to $\frac{1}{2}$-in. round bars are used, while for beam, girder, and column reinforcement, from $\frac{5}{8}$- to $1\frac{1}{4}$-in. bars are ordinarily employed.

The principal objection to the use of plain, round bars in reinforced-concrete work is that they are not gripped, or held, well by the concrete. Plain square and flat bars are sometimes used for the reinforcement of concrete, though, generally, both of these sections, when so used, are deformed by twisting.

(a)    FIG. 2    (b)




In the nomenclature of reinforced concrete, round, rolled sections are designated as *rods*; square sections as *bars*; and rectangular sections as *flats*, or *flat bars*.

In the preceding table are given the areas and weights of square and round bars from $\frac{1}{16}$- to 2-in. sizes.

**Bars of Special Construction.**—Some early forms of bars used in reinforcement of concrete are shown in Fig. 1. That shown in (a) is known as the *Hyatt bar*. In (b) is shown the *Staff bar;* this consists of a flat bar, through which a countersunk punch

(a)

has been partly driven, thus forcing the metal out on the opposite side so as to form projections. The *De Mann bar* is shown in (c).

There are numerous bars on the market having special mechanical bonds. The complete descriptions of such bars can be obtained from their manufacturers. Only a few will be mentioned here as examples.

**Square-Twisted Bars.**—The square-twisted bar consists of a square bar that is twisted by being given a certain number of turns around its axis, either while it is hot or while it is cold; this bar is often known as the *Ransome bar*. By twisting the bar to the screw shape, as shown in Fig. 2 (a), a form is obtained that has great resistance to pulling from a mass of concrete. If the square bars are twisted cold, their elastic limit and ultimate strength are increased from 8 to 25%. The square-twisted bar can be obtained in various sizes for various purposes.

$\frac{3}{4}'' \times 2\frac{7}{8}''$ Bar-Weight = 2.7 lb. per foot-Area = 0.79 Sq. in.

(b)

FIG. 3

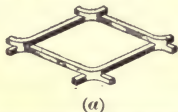
**Corrugated Bar.**—In Fig. 2 (b) is shown a corrugated bar known as the *Johnson bar*, after its inventor, A. L. Johnson. The corrugations on the sides, of course, increase greatly over smooth bars the grip on the concrete.

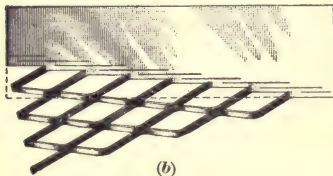
**Kahn Trussed Bar.**—Fig. 3 (*a*) shows the Kahn Trussed Bar. The section of one of these bars is shown in (*b*).

(*a*)

(*b*)

FIG. 4

The fins are partly sheared across and also in a direction parallel with the axis of the bar, and are bent up, as shown in (*a*), so as to form a grip with the concrete and to provide the stirrups, or web members, necessary to resist diagonal stresses. The Kahn bar is made in various sections.




**Expanded Metal.**—One form of metallic reinforcement for concrete is the distorted steel plate known as *expanded metal*, a familiar illustration of which is shown in Fig. 4 (*a*). This form of reinforcement is manufactured by partly shearing a sheet of steel in parallel rows, as shown in (*b*), and then pulling the material sidewise, thus forming a diamond mesh. In this way, the area of a sheet is increased about eight times, with a corresponding decrease in weight per unit area and without any waste of material. The material is made in various sizes. Various forms of metal lath are to be had.

**Woven Wire.**—Various forms of wire cloth, or woven wire, are also on the market. Among them is *Clinton wire cloth*. It is a fabric that is secured at the intersections by a perfect, electric weld, and it has at intervals a double wire that twines in and out, as shown at *a*, Fig. 5.

**Floor Systems.**—A complete floor system constructed of loose rods is shown in Fig. 6. The beam reinforcement consists of three reinforcing rods. Two of these rods *a* run straight through the entire length of the beam, while the third *b* is bent upwards at the ends. This bent member provides tensile resistance at the top of the beams and thus takes care of the negative bending moment, which occurs in all beams fixed at the end. The bend in such rods is usually made at an angle of about 30° with the horizontal. The rods should be straight at the center of the span for at least one-third the distance between the supports.

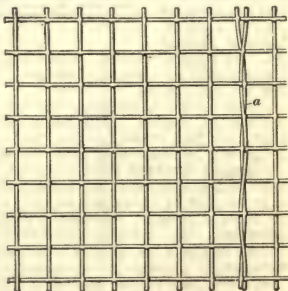
A tie-rod *c*, that is 4 or 5 ft. in length, and sometimes bent down at the ends, should be placed over the top of the beam juncture.

The girder reinforcement consists of five rods, two of them *c* being bent up to provide against negative bending moment.

In the best work, two short rods *f* are located transversely through the column. These rods tie the adjoining girders together and provide additional rigidity at the junction of the girders with the column.

The slab rods *h* are generally spaced at about 6 in. from center to center. They should bond with the stirrups, or web reinforcement, of the beams, and may be threaded through, interlocked, or wired to them. It is customary to provide shrinkage rods that extend at right angles to the regular slab reinforcement, in order to prevent shrinkage cracks in the concrete. For this purpose, ¼-in. round or square rods *j* are generally spaced about 2 ft. from center to center. In order to bond the concrete over the main girders securely, it is also good practice to provide over these important members rods *d* of about the same size as the slab rods. These rods should run through holes punched in the top of the stirrup, as illustrated at *g*, and should extend at right angles to the axis of the girder. Sometimes, similar rods are used in the slab over beams, as shown at *k*.

FIG. 5

The longitudinal reinforcement of the concrete columns consists of four round rods *l*. It is customary to project them above the concrete of each story about a foot and to splice them by lapping and wiring or by using pipe


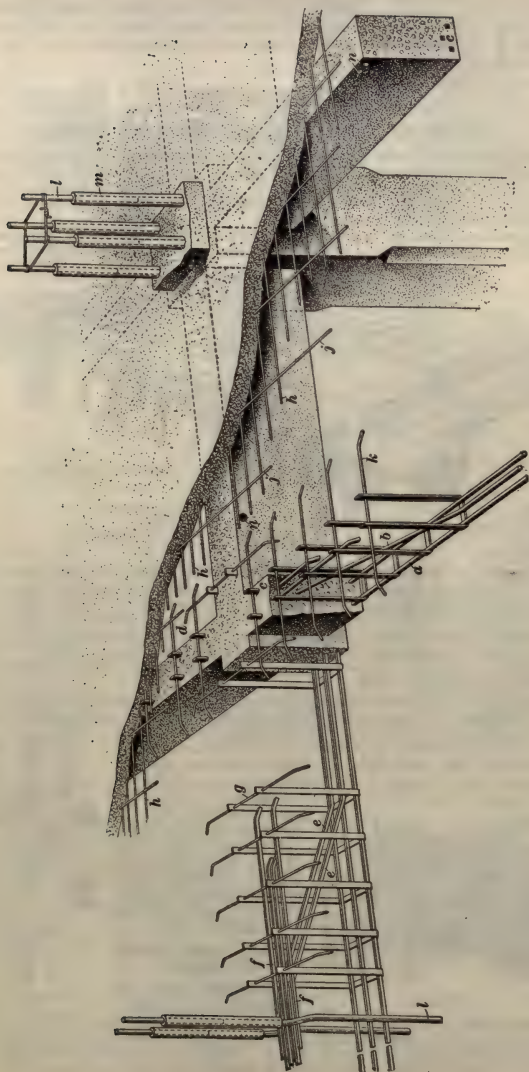


Fig. 6

sockets $m$, as illustrated. Frequently, it is not possible to lay out beforehand the electric-light or power wiring, but if this installation is to be adopted $1\frac{1}{4}$-in. pipes to serve as a passageway should be embedded near the center of the span of all beams and girders close to the under side of the slab construction, as at $n$.

# FORM WORK

## CONSTRUCTION AND FINISH OF FORM WORK

In the erection of reinforced-concrete work, nothing requires more careful consideration than the construction of the *form work*, or molds, necessary to shape and support the concrete until it has thoroughly set and hardened. Throughout the practice of reinforced-concrete construction various methods of form constructions are in use.

The greatest economy is gained by constructing the forms so that they can be used over and over again in the structure. Economy in construction can

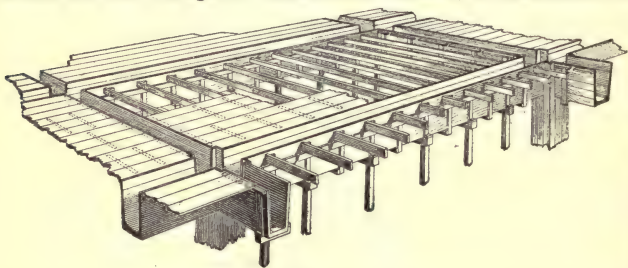

Fig. 1

also be gained by fastening the form work together with a minimum amount of nailing. Every nail that is driven gives trouble when the forms are taken down to be replaced for the upper floors. In many constructions, wedges and clamps are used instead of nails or screws if the forms are to be reused.

In some instances, both wooden and metal forms are coated on the side next to the concrete in order that the forms may be detached more readily. Coating the forms also serves to prevent the marking of the grain of the wooden forms on the finished concrete work.

Dead oil, or crude petroleum, has been used with success for this purpose. It is not unusual to soap wooden forms, and in some cases tallow and bacon fat have been employed. The latter is especially recommended for coating metal forms, as it seems to give the best results with forms of this material. In some instances, wooden forms have been covered on the inside with paper, and even canvas has been used, although it is usually found that the paper adheres to the concrete work and is detached only with difficulty. It is not customary, however, to oil or coat the forms unless they are to be used for fine exterior work.

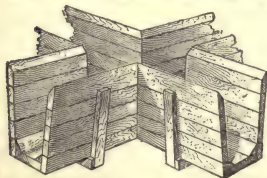

Fig. 2

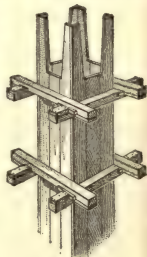
Fig. 3

## FORMS FOR FLOOR SYSTEMS

**Common Types of Form Work.**—In Fig. 1 is shown a type of form work extensively used for the construction of reinforced-concrete floor systems, and in Fig. 2 is shown a perspective of the forms at the intersection of a beam and girder. This form work is designed so that light $\frac{7}{8}$-in. dressed tongued-and-grooved material may be used extensively in its


construction. It is so arranged that the sides of the beams and girders, together with the slab form boards, may be removed without the necessity of

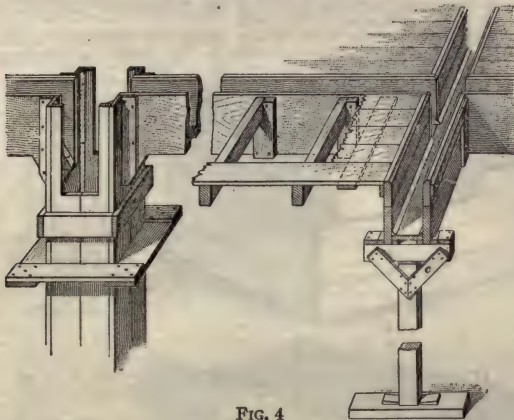


Fig. 4

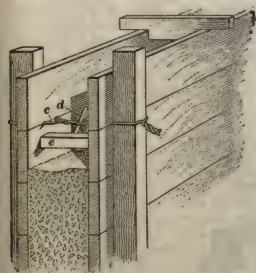
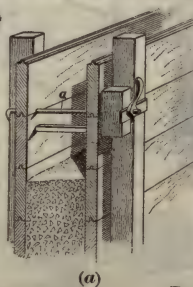
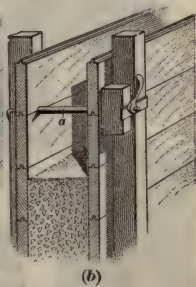
removing the supports directly underneath the beams and girders. The form for columns in this type of construction is shown in Fig. 3.

Fig. 5

Fig. 6

(a) (b)






**Forms Constructed of Plank.**—A superior type of form for a reinforced-concrete floor system is shown in Fig. 4. The wooden forms are supported by 3″×4″ studs. As it is important to bring the forms to a true level, a double adjustment wedge is provided at the bottom of the studs. The forms for the columns are made of 1½- or 2-in. material. In the construction of the beam and girder forms 2-in. planks are generally used for the sides. In order to form a chamfer on the lower edges of the beams and girders, triangular fillet pieces are nailed in the forms. It is customary in this type of construction to make the forms for the slabs of ⅞-in. plain boards, frequently using tongued-and-grooved material for the purpose.

Fig. 7

**Wall Forms With Wire Ties.**—A type of wall-form construction that is frequently used is illustrated in Fig. 5. In order to prevent the sides of the

forms from spreading when the concrete is tamped in place, a wire tie *c* is used. This tie is made taut by twisting with a bar, or stick *d*. To keep the form boards the proper distance apart for the thickness of the wall, a block or stick *e*, of wood is sometimes inserted.

**Wall-Form Construction With Clamp Bolts.**—A wall-form construction similar to that shown in Fig. 5 is illustrated in Fig. 6 (*a*). In this form, how-

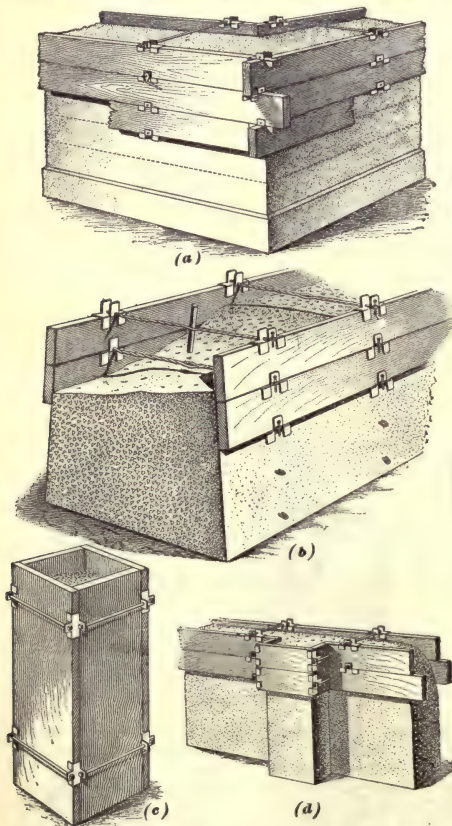
(*a*)

(*a*)

(*b*)

(*b*)

(*c*)          (*a*)

(*e*)


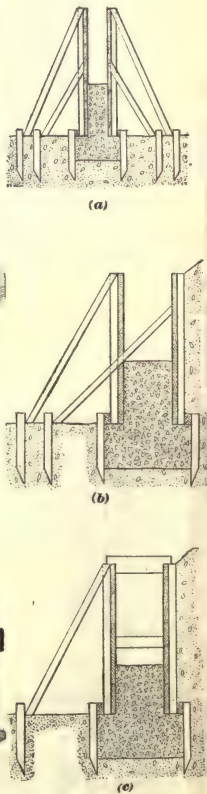


FIG. 8                                    FIG. 9

ever, a clamp bolt *a*, instead of a wire tie, is used to prevent spreading. If a bolt of this character is used, it must be knocked out before the concrete has finally set and when the form boards are to be raised to form the next course of concrete. The bolt is preferable to the wire tie, because it is removed from the concrete. Wire ties are usually cut off close to the concrete work after the form boards have been removed, and as the ends frequently project, they rust and thus stain the wall.

In (b) is shown the construction of a wall form in which a pipe separator *a* is used with the clamp bolt. The pipes may be driven out of the concrete after it has obtained its initial set, or they may be left in place.

**Clamping Devices and Plank Holders for Wall Forms.**—Many devices that aid in the construction of concrete walls have been invented. One of the most useful of these devices is the *Sullivan pressed-steel plank holder*, various forms of which are shown in Fig. 7. These holders are formed from an iron plate by shearing and bending it so as to form clips. The application of this type of plank holder is illustrated in Fig. 8.

**Braces for Wall Forms.**—If a wall is to be constructed in a place where there is no embankment, a double set of forms braced as shown in Fig. 9 (a) must be used. If the soil of an embankment against which a concrete wall is to be built is unstable, it is necessary to sheath and brace it. This may be accomplished in the manner shown in (b) or (c).

## CONCRETE MIXERS

In the construction of a reinforced-concrete structure, the quantity of concrete to be placed decides the amount of equipment and the character of the machinery that is to be employed. The character of the work also influences these two factors. In all instances, the concrete plant should be equipped with machinery suitable for the size of the work and the number of men that will be available in the construction operation. On small work, the concrete is frequently mixed by hand; it is, however, unusual for the concrete in large operations to be so mixed. The successful contractor will employ the mixing machine that is found most efficient and will give careful attention to its erection in the field.

There are many kinds of concrete mixers in commercial use. These mixers are classified according to the principles upon which they operate, and are known as *batch mixers* and *continuous mixers*.

Frequently, the selection of the mixer, especially in work where new equipment is to be used, is left to the superintendent. In making the selection, the superintendent should bear in mind the character of the work; that is, whether it is of more importance to turn out great quantities of concrete than it is to have a uniform mixture, or whether, as in a reinforced-concrete building, the most important consideration is to have concrete delivered from the mixer of uniform consistency. Usually, for heavy mass work the continuous mixer is advantageous, but the batch mixer is now more used for work such as that included in ordinary reinforced-concrete buildings.

The batch mixer often consists of a metal box in the shape of a cube, a cylinder, etc. The materials are put in this box and are mixed by revolving the box on a horizontal axis. There are often deflectors on the inside of the box to help in mixing. The machines are sometimes discharged by tipping them until the contents slide out of an opening or by other suitable means.

The continuous mixer often consists of a trough or cylinder or long box square in section. The materials enter continuously at one end and are discharged mixed at the other. They are usually mixed, in their passage through the machine, by paddles or deflectors, or by revolving the cylinder or box. The ingredients are often moved from the receiving to the discharging end of the machine either by the trough or cylinder being tilted or by paddles that gradually force the mass in one direction.

## CONCRETE STRUCTURES

It is proposed to mention briefly a few of the uses in engineering to which concrete can be put. Complete examples of work with all details cannot be given in such a short space, but the few words and illustrations may suggest to the designer ideas that may be elaborated and changed to suit various conditions. The calculations of stresses and proportioning of parts is beyond the scope of this work. They should be left to a competent designing engineer.

**Tank Tower of Reinforced Concrete.**—The tower shown in Fig. 1 was designed to carry a 200,000-gal. steel tank. The tower consists of eight concrete columns spaced on centers around the circumference of a 26½-ft. circle and surrounding a hollow concrete cylinder with an inside diameter of 8 ft. The columns and cylinders are held together by two intermediate platforms

and a heavy platform, or slab, at the top. The footing is spread over the entire base of the tower, and is in the form of a sixteen-sided polygon, being 6 ft. in thickness and 38 ft. in diameter at the bottom. The central shaft, in addition to carrying some of the load of the tank, acts as a cylinder around which the reinforced-concrete stairs are run and likewise forms a shaft for the pipes leading to and from the tank. The columns of the lower tier are 3 ft. 6 in. square; those of the second tier 3 ft. square; and those of the top tier, 2 ft. 6 in. square. The offset is made at the outside of the column, as shown in Fig. 2.

The details of construction and the method of reinforcing the columns, cylinder, and balcony floor construction are illustrated in Fig. 3, a half plan of the structure being shown in (a), and a section through the column construction, balcony, and cylinder, in (b). As will be observed, the thickness of the cylinder is dropped off 3 in. at each tier; thus, the walls of the cylinder at the bottom are 18 in. in thickness, and at the second and the third tier they are 15 in. and 12 in., respectively. The reinforcing rods are likewise reduced in size in both the columns and the cylinder from the first tier upwards. In the lower tiers, the columns have four 1¾-in. round rods; in the second tier, four 1⅝-in. rods; and in the upper tier, four 1⅜-in. rods. The vertical reinforcing rods are placed near the corners of the columns and are tied in with ¼-in. wire ties placed 12 in. from center to center. These rods were figured in estimating the compressive strength of the columns. Their ends are neatly fitted and are surrounded with a pipe sleeve. The bottom rods project into the reinforced-concrete footing and are slipped into pipe

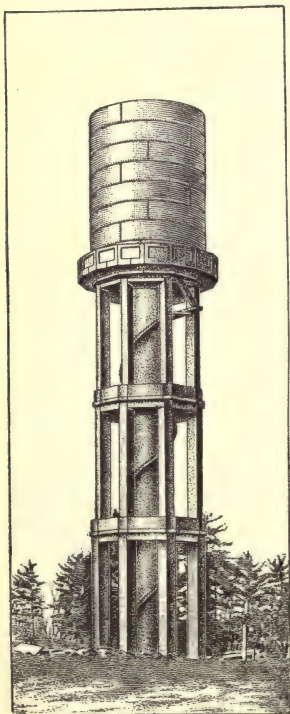

FIG. 1

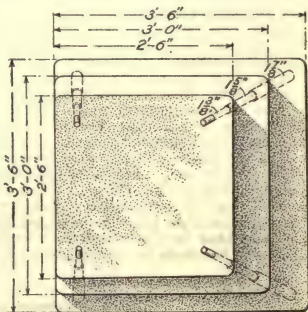

FIG. 2

sleeves provided with a 12-in. circular cast-iron base. In this way, the bearing strength of the bars was well realized. The cylinder is reinforced with vertical rods placed about 12 in. from center to center, and horizontal reinforcement, consisting of 1-in. hoop rods, is also provided in it. The balcony floors are reinforced with rods that radiate from the cylinder and bear upon the concrete lintels spanning the space between the columns, each of these lintels being reinforced with four corrugated bars. The floor of the third balcony, which carries the tank, is about 36½ ft. in diameter and 16 in. in thickness. It is heavily reinforced with radiating 1-in. rods, and is cantilevered about 4 ft. beyond the

column. At each balcony is provided a monolithic railing, or balustrade. This railing is about 3 ft. high and 6 in. in thickness and is reinforced. In the construction of this work, a 1–3–5 mixture was used for the foundation and a 1–2–4 mixture, placed very wet, was employed for the rest of the construction. The aggregates used throughout the construction were sand and good,

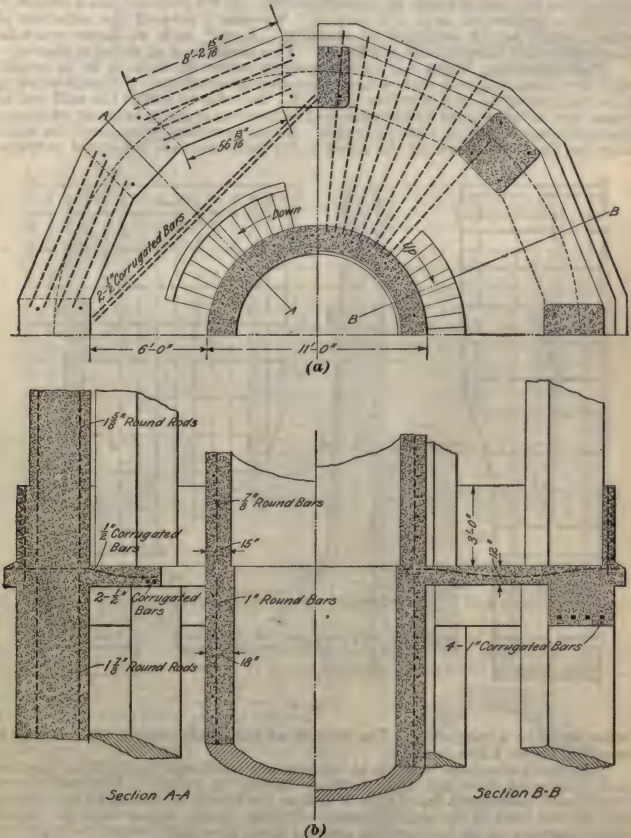

Fig. 3

clean gravel, which, being very coarse, took the place of broken stone. No effort was made to finish the structure after erection, but in placing the concrete a very wet mixture was used. It was thoroughly spaded along the sides of the forms, so as to force the gravel away from the surface and allow the neat cement to mold smooth against the form boards. The work that resulted was smooth and presentable.

**Reinforced-Concrete Retaining Walls.**—Fig. 4 shows a retaining wall of moderate height. The base is spread out at $AB$ so as to make the wall less easily tipped. The earth behind the wall resting on the part $B$ has to be lifted if the wall tips, so this earth also assists in preventing the wall from turning over. The part $A$, called the *toe*, extends out in front of the wall, and by increasing the lever arm of the loads also tends to prevent tipping. The load of earth on the part $B$ tends to prevent sliding. If the wall still has a tendency to slide, a projection, as at $c$, is put on. Weepers $d$ prevent the collection of water, which would endanger its stability. A wall such as shown must be thoroughly and scientifically reinforced. One method of so doing is shown.

**High Retaining Walls.**—If retaining walls are to be over 12 ft. in height, they are often designed with a buttress every 10 or 12 ft. A design suitable for a high retaining wall is shown in Fig. 5. In order to stiffen the wall and to cause it to act merely as a slab subjected to transverse stress between supports, the buttresses shown at $a$ are provided. As the resultant pressure of the earth is in the direction shown by the arrow $b$, the buttresses are subjected to trans-

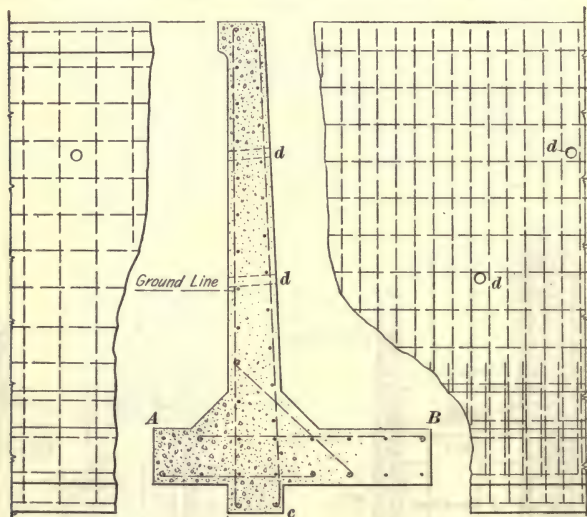

FIG. 4

verse stress as a cantilever. The tension at the inside edge of the buttress is provided for by Kahn bars $c$.

The wall spans from buttress to buttress are reinforced in the same manner as a reinforced floor slab span between beams or girders. The wall is reinforced with horizontal Kahn bars $d$ and as the thrust of the earth per square foot on the back of the wall increases with the depth, these bars are placed closer together at the bottom, the spacing being increased toward the top.

To prevent its failure, the footing is reinforced along the inside edge with the beam $e$. This beam is monolithic with the buttress, so that the footing is logically reinforced with transverse bars $f$. In order that the entire design may be stiffened and strengthened, gussets or fillets are inserted in the junctions between the buttresses and the footing. To reinforce the footing further, longitudinal bars $g$ are provided. Additional reinforcement $h$ running in a vertical direction is provided in the wall.

**Conduits.**—Reinforced concrete is used for such constructions as water conduits, sewers, aqueducts, etc. A type of conduit for carrying water is

shown in Fig. 6. As will be observed, it is reinforced with expanded metal. In nearly all instances, such conduits are constructed with collapsible centering

PLAN

SECTION AT A-B

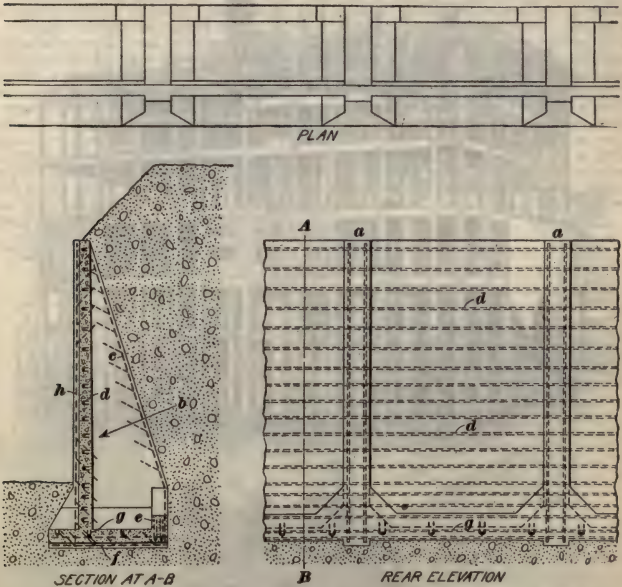
REAR ELEVATION


FIG. 5

inside, and with forms and lagging for the outside work. The work is always carried along in sections.

**Coal Breakers in Reinforced Concrete.**—The Taylor coal breaker was the first all reinforced-concrete breaker constructed in the anthracite fields, although the Pine Hill breaker, at Minersville, Pa., was built in 1906, of reinforced concrete from the foundations to the main breaker floor, including the coal pockets, slate pockets, and shaker and jig supports.

Under favorable conditions, the average wooden anthracite breaker has a life of about 20 yr., but mostly conditions are unfavorable to such longevity, and this, coupled with the rapidly advancing price of timber suitable for such structures, has caused engineers to consider the more durable iron and reinforced concrete as building materials. Wherever anthracite is prepared wet, the decay of the timbers is hastened.

The rear of the breaker in the course of construction is shown in Fig. 7. The first two rows of posts in the rear of the breaker are about 2 ft. square and up to the second or pocket floor have a length of 65 ft. Directly under and between the pockets, where the most weight will come, the 2-ft.-square posts are supplemented with 36-in.-square posts. As the posts are

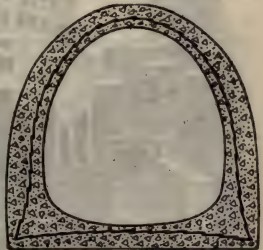

FIG. 6
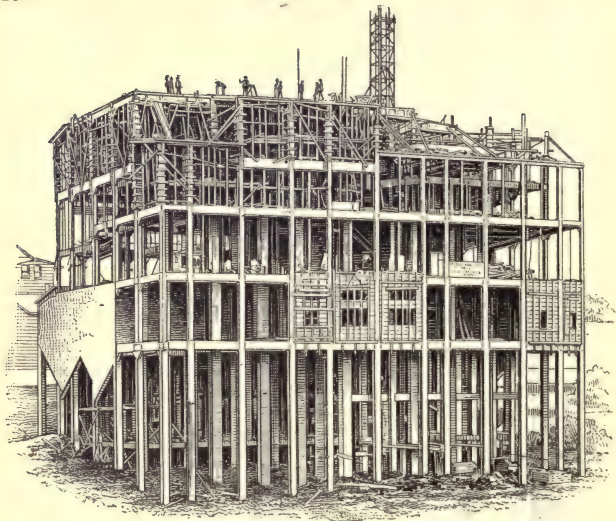

FIG. 7

FIG. 8

carried upwards this size is decreased until at the top floors they are but 12 in. square.

In Fig. 8 the breaker is shown practically finished with the top forms still in place, and as it looks today from the outside, could be taken for an office building. It will be noted that the architect has furnished windows for daylight; also each post is supplied with tubes for wiring for electric lights, thus making this breaker an exceptional one for light and comfort of the employes. In the construction of the posts and beams, corrugated rods $1\frac{1}{2}$ in. in diameter were placed at each corner, then bound with hoop bands and wire so as to form a rectangular cage. They were reinforced by smaller corrugated iron rods from $\frac{5}{8}$-in. diameter up to $1\frac{1}{2}$-in., as the occasion demanded. Inside this cage pipes for the electric wiring were placed and then wooden forms were constructed around these skeleton post frames. Concrete was poured in a little at a time from the top of the forms and tamped with iron rods about the pipes and rods. In this way the posts were built up to the height of a floor, where the rods for the beams were tied with those of the posts. The beams were made the same as the posts.

FIG. 9

It will be noted that the coal pockets are large and provided with two chutes so that two cars can be loaded from the same pocket at the same time. There are fourteen chutes for each track, or twenty-eight for both tracks. To the rear of Fig. 8 is seen the old Taylor breaker, constructed of wood.

It may be of interest to know that while the Taylor breaker is concrete, 500,000 ft. of lumber will be needed inside for machinery bed-plates and other fittings. However, very little if any of this lumber is large sized and there are no sticks such as breaker framing demands.

**Concrete Coal Pockets.**—The Pennsylvania Coal Co. has erected a new breaker at Throop, Pa. In the construction of this breaker both reinforced concrete and steel are used; reinforced concrete for the coal and rock pockets, and part of the washery, and steel for the main part of the building, which will contain the washery.

The capacity of the coal pockets is 3,500 T. The coal cars are to be loaded directly beneath the pockets, while box cars are to pass on the outside of the building and are to be loaded from a chute leading from the center of the bottom slab of the pocket. The slope on the bottom of the coal pockets is 9 in 12 and on the rock pockets 6 in 12. The width of these pockets varies from 10 ft. 8 in. to 16 ft. Where the pocket is not over 12 ft. wide, the floor slab is designed so

as to carry the load without any beam for support. But for the pockets 16 ft. wide a beam is placed beneath the floor slab. Fig. 9 shows a view through the coal pockets of this breaker during construction. The forms, it will be noted, are still in place.

**Concrete Shaft Lining.**—Concrete is now being used to line shafts in mines. As yet there is no uniform method of doing this work and the designs are changed to suit various conditions to be met. The shaft with concrete lining about to be described is the main shaft of the Filbert mine of the H. C. Frick Coke Co.; it is located in Fayette County, Pa.

The shaft, elliptical in plan, measures 13 ft. × 28 ft. in the clear on the center lines of the axes, and has a depth of 550 ft. below the top of the coping to the

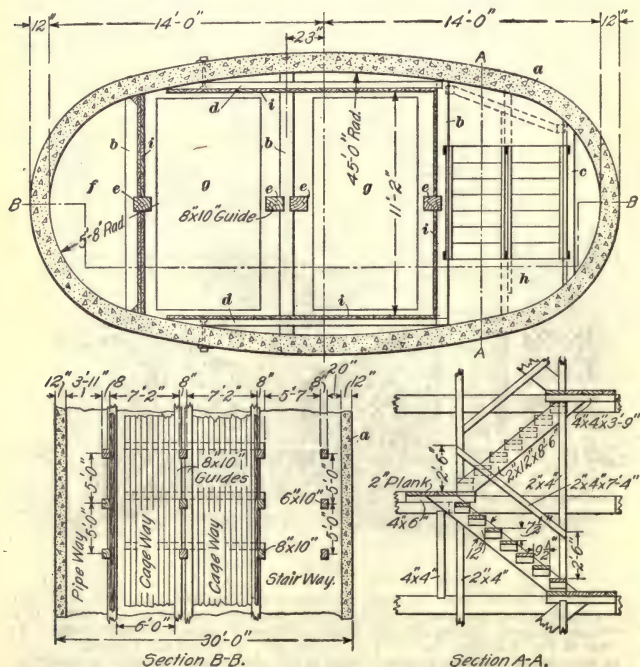
Section B-B.　　　Section A-A.


FIG. 10

bottom of the 9-ft. coal bed, and is provided with a sump 15 ft. below the coal. This shaft is divided into four compartments, containing two cageways, a stair-way, and pipeway.

The plan of the shaft is shown in Fig. 10. At $a$ is shown the concrete lining; at $b$, the $8'' \times 10''$ yellow-pine buntons; at $c$, the $6'' \times 10''$ buntons; at $d$, the $4'' \times 8''$ yellow-pine nailing strips; and at $e$, the yellow-pine cage guides. The compartment reserved for the various pipes that go up the shaft is shown at $f$. The two hoisting cages are shown at $g$. At $h$ is a compartment for foot travel-ing fitted with steps and landings. The hoisting part proper is largely lined with 1-in., yellow pine, tongued-and-grooved sheathing.

The circumference of the inside of the concrete lining is 69 ft., with a clear-opening area of 310 sq. ft., comprising 195 sq. ft. for the two cageways, 80 sq. ft.

for the stairway, and 35 sq. ft. for the pipeway. The ends of the shaft conform to a radius of 5 ft. 8 in. and the curvature of the sides to a 45-ft. radius. From the top of the coping to solid rock, a distance of 19 ft., the structure is of heavy concrete construction forming a solid foundation for the structural steel head-frame of 135 ft. superimposed thereon. Fig. 11 shows the irregular-shaped plan and elevation of this portion of the work. This shaft has two water rings constructed therein; one at 78 ft., and the other at 494 ft. below the top of the coping.

All concrete for lining the shafts is composed of 1 part Portland cement; 2 parts clean, sharp, river sand, and 5 parts of stone crushed to pass through 1½-in. ring. About 50% of the stone used for concrete was obtained from the

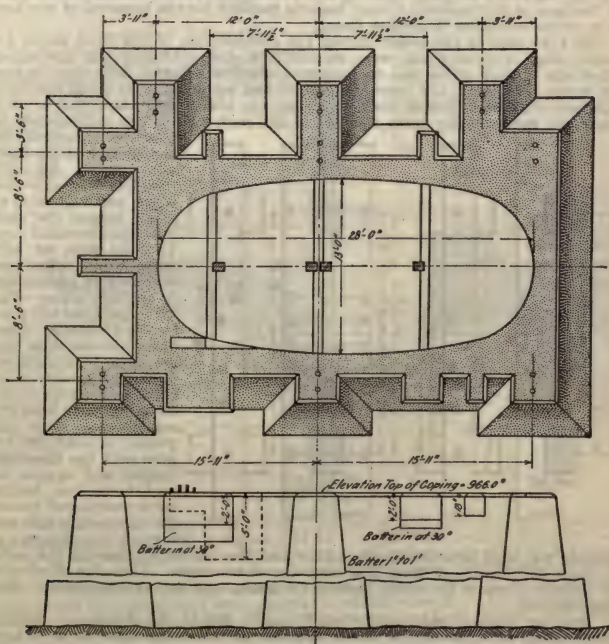

FIG. 11

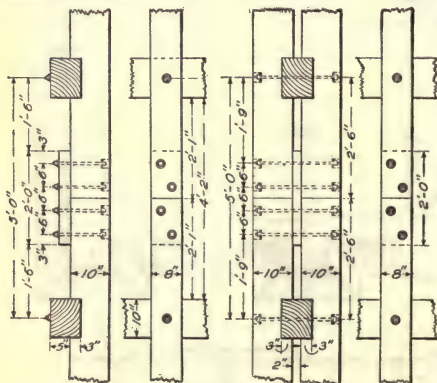
materials excavated from the shafts. About 30% was shipped in, crushed ready for use, while about 20% was obtained from a quarry on the grounds.

In sinking this shaft, an excavation was first made to a depth of 65 ft. All excavating was done to the full measurements of the outside perimeter of the concrete lining, being kept to a correct line by plumb-bobs suspended from a template placed above the opening. Derricks were used to handle the material excavated. At the depth mentioned, the concreting was begun. Forms were put in near the bottom to the height of 5 ft. and filled. Then 5 ft. more of forms were put on top of the first forms and again filled. Then another section was built and filled and so on until the surface was reached. The shaft was then sunk about 50 ft. deeper and concreted up from the bottom in the same way. Then another section of the shaft was sunk, and so on until the job was completed.

The dividing struts for the compartments of the shafts are 8″ × 10″ buntons, spaced vertically 5 ft. center to center. The buntons support the guide rails for the cages—these are 8 in. × 10 in., surfaced on four sides and fastened to the dividing struts or buntons as shown in Fig. 12. The buntons are set in the concrete shaft lining to a depth of 6 in. on each end, allowing from 6 in. up of concrete beyond their ends, thus insuring a water-tight wall. The minimum thickness of the concrete lining wall is 12 in. In soft strata, the concrete is as much as 33 in. in thickness, as no voids were left between the rock and lining, all such being carefully filled with concrete. Bolts for the guides have a 1-in. stud nut and two wrought-iron washers ⅜ in. thick.

Throughout a portion of the shaft, wedge-shaped blocks with a base 6 in. × 8 in. and 4 ft. long, tapering to a point, were placed on the buntons just at the face of the concrete lining, making pockets for the removal of the buntons, when necessary to replace them.

To take care of the water during the construction of the shaft above the water rings, two methods were successfully used. During the concreting, when any flow of water was encountered, sheet-iron plates were used to turn the water away from the concrete until it had set sufficiently so as not to be damaged by water flowing over it. Then the sheets were deflected so as to cause the water to run down the face of the rock wall of the shaft, where, at



intervals around the circumference of the shaft, were placed 3-in. tile pipe set in loose broken stone and extending down behind the shaft lining to the water ring. The tile pipe, set with open joints, took care of the water, conducting it to the water ring. To hold the tile pipes to their proper place and to insure their non-stoppage from concrete packing in around them, sheet-iron strips of No. 22 gauge were bent into semicircular form and placed around the tile pipe with the open side toward and against the rock face; then broken stone was placed around the pipe within this protection. In this way an

**Fig. 12**

opening was kept between the rock face and the tile pipe, allowing the water to reach the drain and thus flow into the water rings. This also eliminated the danger of water gathering behind the lining wall and exerting undue pressure thereon.

Another method successfully used was to locate the fissure or opening where larger streams entered the excavation, and to enlarge them so as to form a reservoir of several cubic feet capacity; then to tightly close the openings of this reservoir with concrete and sheet iron, having placed a wrought-iron pipe of sufficient capacity to handle the water gathered therein. This pipe conducts the water to a pipe set vertically in the lining-wall concrete and leading to the water rings. This latter method was used only where a large flow of water was encountered.

The water rings in the shaft were constructed behind the shaft-lining wall, where a niche was blasted out of the rock to form an opening 2 ft. wide and 4 ft. high throughout the entire perimeter of the shaft. The bottom of this niche was concrete in gutter shape, with a drop of 3 in. from its highest to its lowest point, located at the pipe-compartment end of the shaft. At the lowest point a wrought-iron pipe, 2½ in. in diameter, set through the lining wall on an angle of 45° and protected by strainer plates, connected with a line in the pipe compartment and led the water to a permanent disposal pump. In the shaft-lining wall, on its inner face and throughout the entire perimeter of the wall, and at a point near the top of the water ring, a groove 4½ in. deep and 5 in. from the face

of the groove to the edge of the lip extending 1½ in. beyond the inner face of the wall was constructed to catch any seepage or water from the surface of the lining. This groove and lip has a fall of 3 in. from its highest to its lowest point, where a 2-in. wrought-iron pipe passes through the lining wall on an angle of 45° leading all water caught in the groove to the water ring. Thus, all the water both behind the lining wall and all water on the inner surface is collected in the water rings and thence led to the pumps and expelled from the shaft.

In the shaft, the approaches leading to the shaft bottom from both the loaded and empty sides are of concrete. These are of 18-ft. span having a minimum thickness of 24 in. for side walls and crowns. Each arch extends

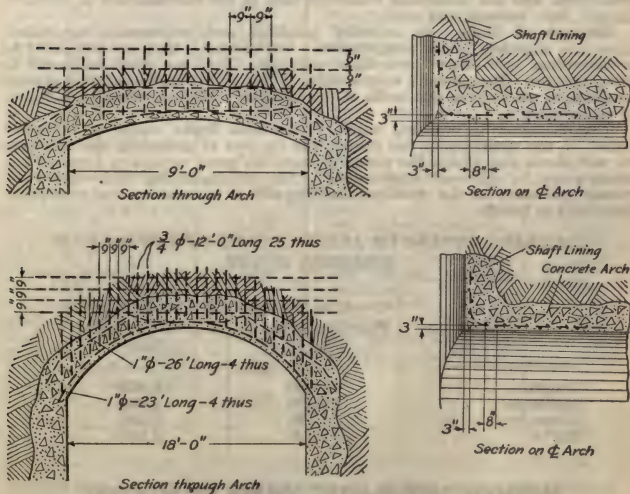


FIG. 13

13 ft. from the face of the shaft lining. Arches of 9-ft. span having a minimum thickness of 18 in. extend a distance of 11 ft. 6 in. from both ends of the face of the shaft lining. These arches connect with the cross-entries and manway around the shaft bottom. An archway of 4-ft. span was placed in the side walls for entrance to the run-around. At the intersection of all arches with the shaft-lining wall, steel bars were placed for reinforcement. The method of this reinforcement is shown in Fig. 13. All centering was built of 2-in. oak plank, spaced 2½ ft. center to center, covered with 2-in. tongued-and-grooved oak lagging. Concreting for the four arches was brought up at one time and also at the same time as the shaft-lining wall was placed.

# MASONRY

## MATERIALS OF CONSTRUCTION

### STONE

The materials employed in the construction of masonry are stone, brick, terra cotta, and the cementing materials used in the manufacture of mortars; namely, lime, cement, and sand.

**Strength of Stone.**—In ordinary buildings and engineering structures, stones are generally under compression. Occasionally, they are subjected to cross-stresses, as in lintels over wide openings. They are never subjected to direct tension. As a general rule, a stone should not be subjected to a greater compressive stress than one-tenth of the ultimate crushing strength, as found by experiment.

The resistance to crushing varies within wide limits, owing to the great variety in the structure of the stones; the method of preparing and finishing the test pieces also affects the results; hence, the great variations found in the values given by different experiments. The accompanying table shows the average resistance of the principal building stones to crushing and to rupture when used as beams.

### CRUSHING STRENGTH AND MODULUS OF RUPTURE OF BUILDING STONE

| Stone | Crushing Strength Pounds per Square Inch | Modulus of Rupture Pounds per Square Inch |
|---|---|---|
| Granite............. | 15,000 | 1,800 |
| Sandstone........... | 10,000 | 1,200 |
| Limestone........... | 13,000 | 1,500 |
| Marble............. | 14,000 | 2,160 |

### MINIMUM SAFE-BEARING VALUES OF MASONRY MATERIALS

| Materials | Safe-Bearing Value Tons per Square Foot |
|---|---|
| Granite, capstone................................ | 50 |
| Squared masonry............................ | 25 |
| Sandstone, capstone............................ | 25 |
| Squared masonry........................... | 12 |
| Rubble, laid in lime mortar................. | 5 |
| Rubble, laid in cement mortar.............. | 10 |
| Limestone, capstone......................... | 36 |
| Squared masonry........................... | 18 |
| Rubble, laid in lime mortar................. | 5 |
| Rubble, laid in cement mortar.............. | 10 |
| Bricks, hard, laid in lime mortar.............. | 7 |
| Hard, laid in Portland cement mortar...... | 14 |
| Hard, laid in Rosendale cement mortar...... | 10 |
| Concrete, 1 Portland, 2 sand, 5 broken stone... | 10 |

## ULTIMATE UNIT CRUSHING STRENGTH OF VARIOUS STONES AND STONE MASONRY PIERS

| Material | Compressive Strength Pounds per Square Inch | Material | Compressive Strength Pounds per Square Inch |
|---|---|---|---|
| Granite, Colo............ | 15,000 | Limestone, Marquette, Mich............... | 8,000 |
| Granite, Conn........... | 14,000 | Limestone, Conshohock- en, Pa.............. | 15,000 |
| Granite, Mass........... | 16,000 | | |
| Granite, Me............ | 15,000 | Marble, Montgomery Co., Pa............. | 11,000 |

| Limestone (oolitic), Bed- ford, Ind. ........... | 8,000 | | |

## ULTIMATE CRUSHING STRENGTH OF BRICK MASONRY PIERS
(*Average Age of Brickwork, 6 Mo.*)

| Material | Composition of Mortar | Compressive Strength Pounds per Square Inch |
|---|---|---|
| Wire-cut brick.................. | 1 cement, 5 sand | 3,000 |
| Dry-pressed brick............... | 1 cement, 5 sand | 3,400 |
| Dry-pressed brick............... | 1 cement, 1 lime, 3 sand | 2,300 |
| Repressed brick................. | 1 cement, 5 sand | 1,700 |
| Light-hard, sand-struck brick...... | 1 cement, 5 sand | 1,900 |
| Light-hard, sand-struck brick...... | 1 cement, 7 sand | 853 |
| Hard, sand-struck brick........... | 1 cement, 1 sand | 2,100 |
| Hard, sand-struck brick........... | 1 cement, 1 lime, 3 sand | 1,500 |
| Hard, sand-struck brick........... | 1 cement, 5 sand | 1,200 |
| Sand-lime brick................. | 1 cement, 3 sand | 1,100 |
| Sand-lime brick................. | 1 lime, 3 sand | 450 |
| Sand-lime brick................. | Neat cement | 1,400 |
| Terra-cotta work................ | 1 cement, 3 sand | 2,000 |

**Absorptive Power of Stone.**—The absorptive power of a stone is a very important property, a low absorption generally indicating a good quality. The accompanying table gives the average percentage of water absorbed by stones.

### ABSORPTIVE POWER OF STONE

| Stone | Absorptive Capacity Per Cent. |
|---|---|
| Granites......... | .066 to .155 |
| Sandstones...... | .410 to 5.480 |
| Limestones...... | .200 to 5.000 |
| Marbles......... | .080 to .160 |
| Trap............ | .000 to .019 |

**Durability of Stone.**—The following rough estimate, based on observations made in the city of New York, indicates the number of years a sound stone may be expected to last without being discolored or disintegrated to such an extent as to require repairs:

|  | *Life of Stone* |
|---|---|
| *Name of Stone* | *Years* |
| Coarse brownstone.... | 5 to 15 |
| Compact brownstone.. | 100 to 200 |
| Limestone........... | 20 to 40 |
| Granite.............. | 75 to 200 |
| Marble.............. | 40 to 200 |

## BRICK

**Size and Weight.**—The dimensions of bricks vary considerably. The standard adopted by the National Brickmakers' Association is, for common clay brick, $8\frac{1}{4}$ in. $\times 4$ in. $\times 2\frac{1}{4}$ in., and for face or pressed brick (clay) $8\frac{1}{4}$ in. $\times 4\frac{1}{4}$ in. $\times 2\frac{1}{4}$ in. The weight of a common clay brick is about $4\frac{1}{2}$ lb.; that of a pressed-clay, enameled brick, about 7 lb. Enameled and glazed bricks are made in two sizes: English size, 9 in. $\times 3$ in. $\times 4\frac{1}{2}$ in.; American size, $8\frac{3}{8}$ in. $\times 2\frac{1}{4}$ in. $\times 4\frac{1}{2}$ in. The usual dimensions for firebricks are 9 in. $\times 4\frac{1}{2}$ in. $\times 2\frac{1}{4}$ in.; various sizes and forms are made to suit the required work. The dimensions of the lime-sand bricks are $8\frac{3}{8}$ in. $\times 4\frac{1}{4}$ in. $\times 2\frac{13}{16}$ in. The weight varies between 5 and 6 lb. The accompanying table gives the approximate weight and resistance to crushing of brick.

### WEIGHT AND STRENGTH OF BRICK

| Kind of Brick | Weight Pounds per Cubic Foot | Crushing Strength Pounds per Square Inch |
|---|---|---|
| Best pressed-clay...................... | 150 | 5,000 to 15,000 |
| Common hard-clay..................... | 125 | 5,000 to 8,000 |
| Soft-clay............................. | 100 | 450 to 600 |
| Lime-sand............................ | 120 | 3,600 to 7,600 |
| Firebrick............................. | 120 | 1,000 to 1,500 |

**Requisites for Good Brick.**—Bricks of good quality should be of regular shape, with parallel surfaces, plane faces, and sharp square edges. They should be of uniform texture; burnt hard; and thoroughly sound, free from cracks and flaws. They should emit a clear ringing sound when struck a sharp blow. A hard well-burned brick should not absorb more than one-tenth of its weight of water; it should have a specific gravity of 2 or more. The crushing strength of a brick laid flat should be at least 6,000 lb. per sq. in. The modulus of rupture should be at least 1,000 lb. per sq. in.

# WIRE ROPES*

## GENERAL DESCRIPTION

### WIRE-ROPE MATERIALS

Wire ropes are used about mines chiefly for hoisting from shafts, for haulage and the transmission of power, for the cables of aerial tramways, for the guy ropes of derricks and smokestacks, etc., and, rarely, for the cables of small, short-span, suspension bridges, as where the town or settlement is situated on the opposite side of a narrow stream from the mine. While wire ropes are now almost universally made of steel, manufacturers still make and list iron ropes, which have a limited field of usefulness.

*Swedish*, *Swedes*, or *charcoal-iron* ropes are made of a very pure wrought or puddled iron having a tensile strength of from 50,000 to 100,000 lb. per sq. in. These ropes are soft, tough, and pliable, and are adapted especially for passenger elevators, small hoists, steering gear of vessels, etc., where the loads are intermittently applied and are not too great, or where the speed is high and the bending stresses great. It will be noted from tables given later that the ultimate breaking strength of a $6 \times 19$ Swedish iron hoisting rope 1 in. in diameter, is but 14.5 T., whereas, the breaking strength of a steel rope of the same kind and size is from 30 to 45 T. For general mine use, iron ropes have been almost entirely superseded by steel ropes because of their greater strength and elasticity.

*Steel ropes* are generally made of open-hearth steel having a tensile strength of from 150,000 to 275,000 lb. per sq. in. and in some cases even more, the tensile strength depending on the composition of the metal and the method of its treatment. Steel ropes are in almost every way superior to iron ropes. The principal advantage is that they have more than double the strength of iron ropes of the same size; consequently, for equal strains, they can be made of much less diameter than iron ropes and can, therefore, be used in connection with much smaller and lighter drums, sheaves, or pulleys. Iron-wire ropes are not so elastic as ropes made of steel wire, hence a larger sheave is required for iron than for steel ropes of the same diameter. Iron ropes, however, are usually more flexible than steel ropes, are less brittle though not so strong, and better resist the acid in mine water. A 1-in. Swedish iron rope has about the same strength as a $\frac{5}{8}$-in. ordinary cast-steel rope; weighs 1.58 lb. per ft. as opposed to .62 lb.; costs (list price) 26c. per ft. as opposed to 16.5c.; and requires a sheave or drum 6 ft. in diameter as against one 2.5 ft. for a cast-steel rope.

*Cast-steel*, *crucible-steel*, and *crucible cast-steel ropes* are the trade names given to the ordinary grades of ropes made from wire having an ultimate tensile strength of 160,000 to 210,000 lb. per sq. in. The breaking strength of a $6 \times 19$ standard hoisting rope of this grade and 1 in. in diameter is given, in the manufacturers' tables, as 30 T., more than twice the strength of a similar iron rope. Ropes of this material are those commonly used in and around mines for haulage and hoisting purposes.

*Extra strong cast-steel*, *extra strong crucible-steel*, *special steel*, and *patent steel ropes* are the trade names for the next stronger grades of ropes, intermediate in strength between cast-steel and plow-steel ropes in strength. The wire from which they are made has an ultimate tensile strength of from 190,000 to 230,000 lb. per sq. in. The breaking strength of a $6 \times 19$ hoisting rope of this grade and 1 in. in diameter is given as 34 T., 11.33% more than that of an ordinary cast-steel rope of the same dimensions. These ropes are also standard and are in general use where it is desirable to increase the factor of safety while retaining the same diameter of rope.

---

*Plow-*, or *plough-steel ropes* are made of wires having an ultimate tensile strength of 220,000 to 250,000 lb. per sq. in. The breaking strength of a $6 \times 19$ hoisting rope of this grade and 1 in. in diameter is given as 38 T., or 11.18% more than that of an extra strong cast-steel rope of the same dimensions. Ropes of this grade are not generally recommended, except where it is necessary to have the maximum of tensile strength with the least weight of rope, or where it is necessary to employ a rope of much greater strength but of the same diameter. The first necessity will arise when hoisting through extremely deep shafts; the second, where by reason of increased loads it becomes essential to have a stronger rope, but at the same time the diameter of the rope is fixed by the size of existing drums, sheaves, etc. Plow-steel ropes are extensively employed for logging lines, dredge and wrecking ropes, ballast unloading ropes, quarry ropes, etc.

*Extra, special,* or *improved plow-steel ropes* are made of wires having an ultimate tensile strength of from 240,000 to 300,000 lb. per sq. in. A rope of this grade of the size cited before has a breaking strength of 45 T., or about 11.84% more than an ordinary plow-steel rope of the same dimensions. The comments upon standard plow steel ropes apply as well to ropes of this grade.

## CONSTRUCTION OF WIRE ROPES

Wire ropes consist of a number of strands, each composed of the same number of single wires twisted around a hemp or wire core or center to form a single rope. The hemp core adds practically nothing to the strength of the rope but, being saturated with lubricant, tends to prevent rusting of the wires and, being soft, acts as a cushion for the individual strands, thus reducing internal friction and wear. A wire core adds largely to the internal friction and consequent wear of rope as the strands rub upon the wire center; increases the weight; and, while adding about 10% to the strength, reduces the flexibility in a marked degree, at the same time adding 10% to the cost. Manufacturers, whose judgment should be final, recommend ropes with wire cores only for standing lines, such as the guy ropes of derricks, etc., because they lack the flexibility demanded of running ropes (those used for hoisting, haulage, etc.), and because of their much greater internal wear in bending around drums, sheaves, and the like.

FIG. 1

**Lay of Ropes.**—The lay of a rope is the direction of the twist of the strands composing it. Ropes are either right or left lay, the former being the ordinary construction as shown in Fig. 1 where the strands are bent to the right. The left-lay construction is shown in Fig. 2.

The term lay is also used to describe the direction of twist of the individual wires composing the strands in a rope. Thus, in Fig. 1, while the rope is right lay (strands twisted to the right), the strands are left lay, the single wires being twisted to the left. Similarly, in Fig. 2, while the rope is left lay, the strands are right lay.

Finally, the term lay is used to designate the pitch of the rope; that is, the rate at which the strands twist or, what is the same thing, the ratio that the length of strand required for one complete turn bears to the diameter of the rope.

In ordinary rope making, the lay or (better) pitch of the wires varies from 2.5 to 3.5 times the diameter of the rope, and that of the strands from 6.5 to 9 times the diameter of the rope. The lay exerts an important influence upon the life of a rope. For the same kind and size of rope, the shorter the lay or pitch, the greater the flexibility

FIG. 2

and elasticity, but the less the strength. This falling off in the strength, due to the shortening of the pitch, is brought about by the nicking, or cutting, of one wire by another, which is naturally less when the ropes cross one another at a long angle (long pitch) than when they cross at a sharp angle (short pitch).

In practice, ropes are commonly classified as ordinary-lay or regular-lay ropes, and as Lang lay or universal-lay ropes. In the *ordinary lay ropes,* which are shown in Fig. 1 and Fig. 2, the wires in the strands are twisted in the opposite direction from that of the strands in the rope, while in *Lang lay ropes,* shown in Fig. 3, the single wires and the strands are twisted in the same

direction. Lang lay ropes may be either right or left twist, and their price is the same as that of ordinary-lay ropes.

The principal advantages of the Lang lay are that, the wires and strands being twisted in the same direction, the surface of the rope is smoother, the outside wires do not so soon become worn as a much longer surface of each wire is exposed to wear, and, the wires being straighter, these ropes are somewhat more flexible. The disadvantages of Lang lay ropes are a tendency to untwist, rendering them unsuited for hoisting except where guides are used; they can be spliced to ropes of ordinary-lay only with difficulty; and when the wires break, the loose ends are very troublesome, because a much greater length of each wire is exposed

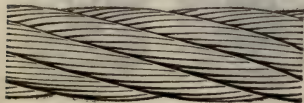
FIG. 3

than in ordinary-lay ropes. Under careful inspection, a regular-lay haulage rope may be used for some time after a few of its wires are broken here and there throughout its length, except when a dangerous risk would be incurred by so doing. The Lang lay ropes are commonly used for haulage, particularly where grips are used to attach the cars to the ropes, and are sometimes used for hoisting, but only where the cage works in guides.

## HOISTING ROPES

### ROUND ROPES

**6 × 19 Ropes.**—Ropes used for hoisting through shafts are round or flat and in either case may be of uniform or tapering section. Round ropes of uniform section, are practically the only ones used in American mines. The standard American hoisting rope, shown in Fig. 1, is composed of 6 strands of 19 wires each (114 wires) wrapped around a hemp center. It is frequently spoken of as a 6 × 19 rope. These ropes are commonly made of cast-steel or, where greater strength is required, extra strong cast-steel. The diameter of sheave recommended for use with a 1-in. rope of this type is variously given at 4 to 4.5 ft.



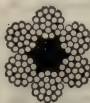


FIG. 1

**8 × 19 Ropes.**—Where extreme flexibility is required, ropes composed of 8 strands of 19 wires each (152 wires) may be employed. From the tables given later, it will be noted that the maximum diameter of rope of this section commonly carried in stock is $1\frac{1}{2}$ in. as against $2\frac{1}{4}$ in. for the 6 × 19. Fig. 2 shows that the core is much larger in proportion to the area of metal than in a 6 × 19 rope of the same size and quality. Consequently, this rope is not so strong as a 6 × 19 rope of the same diameter (24 T. as against 30 T. for 1-in. cast-steel rope) and is more liable to flatten out under heavy pressure. The diameter of sheave suggested for use with a 1-in. rope of this type is variously given as 2.5 to 3.25 ft.;

FIG. 2

FIG. 3

materially less than that required for a 6 × 19 rope. Ropes of this class are recommended for derricks and similar work where small sheaves must be employed, but it should be noted that, so far as the working life of this type is

concerned, the increased flexibility in a very considerable measure offsets its decreased strength.

**6×37 Ropes.**—A form of very flexible rope that is not infrequently used in preference to the 8×19, is shown in Fig. 3; in this, the rope is composed of 6 strands of 37 wires each. As there is a much greater area of metal in proportion to the hemp core than in an 8×19, the breaking strength of a 1-in. cast-steel rope of this type is given as 29 T., only 1 T. less than that of the standard 6×19 rope and 3 T. more than the 8×19. The diameter of sheave suggested for this rope is the same as that for the 8×19;

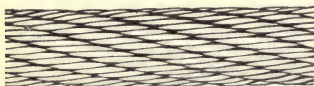

FIG. 4

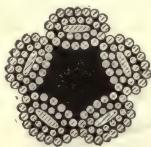
viz., 2.5 to 3.25 ft. As the wires in this rope are, of necessity, smaller than those in a 6×19 rope of the same diameter, it is apparent that this type of rope is not so well adapted to withstand abrasion as those containing larger wires. This rope is employed where the bending strains are very great, as in logging operations, for use with electric cranes, etc. When galvanized, this rope is largely used for hawsers in towing, etc.

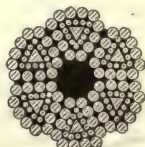
**Non-Spinning Ropes.**—Non-spinning hoisting rope, made by one of the leading manufacturers, is shown in Fig. 4. It is composed of 18 strands of 7 wires each (126 wires), 12 of the strands being laid in a reversed direction about 6 which, in turn, are laid about a hemp core. Because of the reversed directions in which the inner and outer sets of strands are laid, there is no tendency to twist and the rope is, thence, adapted to hoisting where the load is not raised between guides but hangs freely as a bucket in shaft-sinking. The rope is slightly more flexible than the standard 6×19 rope and slightly stronger. However, it cannot be spliced.

**Flattened-Strand Ropes.**—In order to present a larger and smoother wearing surface, and thus to increase the life of the rope, flattened-strand wire ropes have been devised. In these ropes the strands have an elliptic, or triangular, cross-section, depending on the shape of the metal

(*a*)       (*b*)

FIG. 5

center of the strand, and the rope has either a hemp or a wire core. They are made either 5×28 (5 strands of 28 wires each, or 140 wires) as shown in Fig. 5 (*a*), or 6×25 (6 strands of 25 wires each, or 150 wires) as shown in (*b*). These ropes are made of Swedes iron, and of cast-steel, extra strong cast-steel, and extra plow-steel. The breaking strength of a cast-steel rope of this make, 5×28, and 1 in. in diameter is given as 30 T., the same as that of the same size and kind round, 6×19 standard rope. A 6×25 cast-steel rope of this type 1 in. in diameter is given as 33 T., which is greater than that of the corresponding 6×19 round rope and nearly as great as that of an extra strong cast-steel rope. There is claimed for this rope greater flexibility, less liability of the wires becoming brittle, and freedom from all tendency to spin or kink; also that they maintain their form better than round ropes.




**Seale Ropes.**—A form of rope made by some manufacturers and used for hoisting, but possibly better adapted to haulage purposes, is shown in Fig. 6, as it is of the 6×19 type used in standard hoisting

FIG. 6

ropes. This is known as *Seale rope* or *Seale lay rope*, and consists of 6 strands of 19 wires each, in which 9 large wires are twisted around 9 small ones, which in turn surround one of the larger size. This rope is intermediate in flexibility and ability to stand abrasion between the standard ropes of 7-wire (haulage) and 19-wire (hoisting) strands. This type of rope, on account of the large outside wires, will withstand heavy frictional wear and is used on slopes, planes, and cable

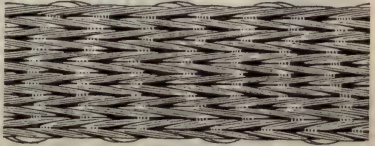
roads where the rope commonly drags, provided, however, that there are no bends of sharp angle to overstrain the outer wires. While there is more metal in the outer wires than in those of the standard rope, there is correspondingly less in the inner wires, and closer inspection of the outer wires is, therefore, necessary to prevent the rope being used too long. The price of these ropes is the same as the standard $6 \times 19$ hoisting rope of the same grade.

## FLAT ROPES

Flat ropes, Fig. 7, are composed of a number of loosely twisted ropes of four wires each and without hemp centers. The ropes, of alternately right and left lay, are placed side by side and are then sewed together with soft iron or annealed steel wire to form a single rope. The sewing wires, which vary in number from 8 to 12 pass through the centers of the individual ropes from side to side and often have to be renewed, as they naturally wear faster than the wires composing the rope proper.

Flat ropes may be made to order of any width to give any desired strength, but the width must, of necessity, be some multiple of the diameter of a single strand. They are made of the same grades of steel as round ropes and, under certain conditions present material advantages over the ordinary type. In very deep shafts

FIG. 7

round ropes have a tendency to twist and untwist, or to spin, something that flat ropes do not do. The width of the reel upon which a flat rope winds is very much less than that of the drum used for round ropes, and as the rope coils upon itself like a ribbon, it tends to equalize the load upon the engine, the effect being approximately the same as that produced by conical drums. Likewise, in hoisting, the rope is always in the same vertical plane, thus avoiding the wear that round ropes are subject to when wound on a drum. Flat ropes are not used in coal mines in the United States, owing to the comparatively shallow depths of the shafts, but are quite extensively used in the metal-mining districts, where vertical lifts of 2,000 ft. and over are common.


## TAPER ROPES

Taper ropes, both round and flat, have been used in deep hoisting. Such a rope has its diameter or width reduced uniformly throughout its length by dropping a single wire at a time, or by decreasing the size of the wire used at regular intervals, so as to reduce the sectional area of the rope in proportion to the weight to be supported. The reason for using taper rope is as follows: When the load is at the bottom of the shaft, the upper part of the rope sustains both the load to be hoisted and the weight of the rope itself. As the rope is wound up, the load on the rope at the drum gradually decreases and, therefore, the size of the rope may be proportionately decreased. Owing to the difficulties of manufacture, taper ropes cannot be made as perfect as straight ropes and their cost is greater; furthermore, they cannot be used for haulage and other purposes when partly worn, as is the case with straight ropes.

---

# HAULAGE ROPES

$6 \times 7$ **Ropes.**—For underground haulage and for the transmission of power, a rope of the section shown in Fig. 1, and either ordinary or Lang lay, is in

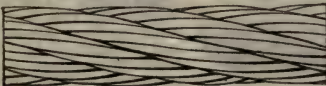


FIG. 1

general use in American mines, to the practical exclusion of any other type. It is composed of 6 strands of 7 wires each ($6 \times 7$) twisted around a hemp center. It is decidedly stiffer

than a $6 \times 19$ standard hoisting rope and requires larger sheaves, as will appear from the tables. Owing to the small number of wires (there are but 42 as against 114, 152, and 222, in the $6 \times 19$, $8 \times 19$, and $6 \times 37$ hoisting ropes) this

rope should be used with a higher factor of safety than is employed with hoisting ropes, as the breaking of one or two wires materially reduces the strength of the rope. These ropes are made of Swedes iron and of the four grades or strengths of steel previously mentioned. As in the case of hoisting ropes, haulage ropes of iron require the use of deceidedly larger sheaves than do those of steel. Manufacturers recommend a sheave from 10.5 to 11 ft. in diameter for a 1-in. iron rope of this type as against a sheave 7 to 8 ft. in diameter for a corresponding steel rope.

**Flattened-Strand Ropes.**—Flattened-strand rope, similar in general construction to the rope of the same name used for hoisting, is also employed for haulage. Ropes of this type are shown in Fig. 2 (a) and (b). The former shows the $5 \times 9$ (45 wires) rope very similar to the $5 \times 28$ hoisting rope of the same type. View (b) shows the $6 \times 8$ haulage rope, which is not unlike the $6 \times 25$ hoisting rope. The ultimate breaking strength of a 1-in., cast-steel, ordinary, haulage rope is given as 31 T., and those of the $5 \times 9$, and $6 \times 8$, flattened-strand rope of the same diameter and material are 31 and 34 T., respectively. The diameter of sheave suggested for the standard $6 \times 7$ 1-in. haulage rope is 7, and 5.75 ft. for either type of the flattened-strand rope. The comments made upon hoisting ropes of this type apply here.

(a)     (b)

FIG. 2

**Seale Ropes.**—Seale lay ropes are used to a certain extent for haulage and those of the Lang lay type are very commonly employed for the same purpose, as explained before.

---

# ROPES FOR MISCELLANEOUS PURPOSES

**Ropes for Cableways.**—Many of the ropes described, and particularly the $6 \times 7$ Lang lay, are used for the track or supporting cable of what are variously known as *cableways, wire-rope tramways, aerial tramways,* and the like. In this system of transportation, the materials to be moved are carried in buckets suspended from wheeled trucks, which are hauled

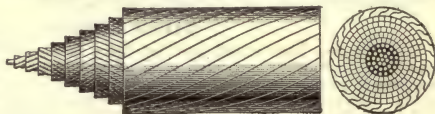

FIG. 1

by a lighter rope upon a fixed rope known as the *cable*, or *track cable*. Such cables are subject to extreme wear and to produce a rope having the maximum of wearing surface, what are known as *locked-wire cables* and *locked-coil cables* have been devised.

The locked-wire construction is shown in Fig. 1. The outside wires are drawn of such a shape as to interlock one with the other, making a smooth cylindrical surface for the carrier wheels to run upon. Ropes of this type have wire cores and are, consequently, stiffer than ordinary ropes of the same size; but as they are proportionally stronger for equal strengths there is probably not much difference in the stiffness of the two forms of construction. The advantages claimed for this rope are lessened wear, both on the part of the rope and on that of the wheels of the traveling carriage; absence of any tendency to twist and turn; and freedom from unraveling should any of the wires break.

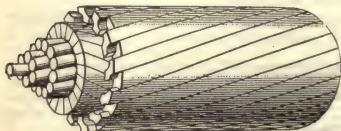

FIG. 2

The locked-coil construction is illustrated in Fig. 2. It differs from the preceding only in the smaller number and larger size of the wires, which makes it stiffer.

Another and cheaper, but very satisfactory, construction for track cables, shown in Fig. 3, is known as the *tramway strand*, or *smooth-coil*. It is merely a heavy strand of very large wires resembling a spirally fluted cylinder in appearance. The large wires give increased durability over smaller wires, owing to the greater surface exposed to wear.

A disadvantage of the track cables here illustrated is that they cannot be spliced. In order to connect them the coupling shown in Fig. 4 must be employed. This consists of two, narrow, tapered sockets, joined at the middle by a plug with right- and left-hand screw

FIG. 3

threads. The ends of the wires are spread apart in the funnel-shaped apertures, and the space between them filled with conical thimbles and narrow wedges made approximately to the shape of the interstices. The sockets are attached to the ends of the cables by a special form of press, after which they are brought nearly together and in line and the proper end of the plug inserted in each. The plug is then turned until the sockets are brought together.

**Ropes for Suspension Bridges.**—Small suspension bridges at mines are frequently built of old and partly worn hoisting or haulage ropes, but a special form of rope, shown in Fig. 5, is not infrequently used for this purpose, particularly if the span is considerable. This is the familiar 6×7 haulage rope, but with a wire instead of a hemp center, which gives increased strength but with lessened flexibility, the latter quality not being of prime importance in bridge construction.

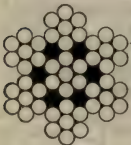
There are many other purposes for which ropes are used in and around mines, such as in running ropes for derricks, aerial tramways, and steam

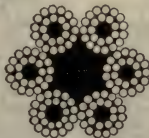
FIG. 4

shovels, as guy ropes for derricks and smokestacks, as rigging, hawsers, and mooring ropes for vessels engaged in the transportation of coal, etc. The forms of some of these ropes are in Figs. 5, 6, 7, and 8.

**Derrick Ropes.**—Guys for derricks and stacks, shrouds and stays aboard ship, etc., are commonly made of ordinary 6×7 rope with a hemp center; though where greater flexibility is required of a 6 strand rope with 12 instead of 7 wires to the strand, that is a 6×12 rope, is used. The wires are commonly single or double galvanized; that is, they receive a single or double coating of zinc to prevent rusting.

**Hawsers.**—Steel hawsers, mooring lines, and running rigging for vessels, which must be more flexible than ropes used for guys, standing rigging, etc., are very commonly made of the 6×37 ropes. Special rope for these purposes is made of the section shown in Fig. 6, in which 6 strands (each with a hemp





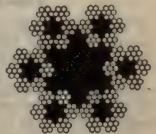


FIG. 5      FIG. 6      FIG. 7      FIG. 8

center) of 12 wires each are wrapped around a common hemp core. Such ropes are very much stronger than those of Manila hemp of the same size and are fully as flexible.

Another form of rope used for the same purposes is shown in Fig. 7. In this case, 6 strands of 24 wires each with a hemp center are wrapped around a common hemp core. This is more flexible than the form shown in Fig. 6 and

is consequently well adapted for mooring lines, which must be wound upon capstans, piles, etc. of comparatively small diameter. The strands vary in their make-up; with some manufacturers, the 24 wires are all of the same size, while with others, the 12 inner wires are considerably smaller than the outer ones, as in Seale lay ropes.

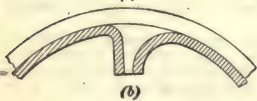
*Tiller rope* is made of six small 6×7 ropes laid around a hemp center as shown in Fig. 8. Containing 252 wires, this is the most flexible wire-rope made. It is used mostly for steering or tiller ropes on steamers, for hand-lines on passenger elevators, and in any place where a smooth and very flexible rope is required. The ultimate strengths of tiller ropes are about one-third less than those of standard 6×19 wire ropes of the same size and grade. The minimum diameter of sheaves recommended for usual loads are: for iron, 30 times the rope diameter; for steel, 25 times the rope diameter. Owing to the small size of the wires, tiller rope should be subject to as little abrasion as possible.

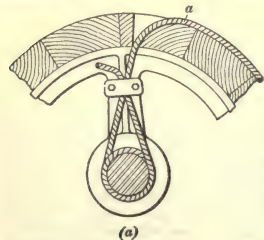
With the exception of tiller rope, and that only when used for passenger elevators, the ropes that have been described are but rarely made of Swedes iron, steel giving much better results. These ropes are almost always galvanized, at a cost of about 10% above that of untreated ropes.

For use in and around oil wells, ropes of 6×7, 6×12, and 6×19 construction are commonly employed. The 6×7 is used for sand lines and, when left-lay, for cleaning out or redrilling wet holes. Casing lines and drilling lines for new holes, the latter left-lay, are made of 6×19 rope.

# ROPE DRUMS AND FASTENINGS

**Fastening Rope to Drum.**—A common method of fastening a rope to a drum is shown in Fig. 1 (*a*), where the rope is passed through a hole in the drum shell and then around the shaft, clamping the end to the rope between the shaft and the shell, as shown. Care should be taken to make the radius of curvature of the hole at *a* as large as possible, so that the wire will not be bent any sharper than is necessary.





When an iron drum is used, the thickness of the rim does not afford enough depth in which to bend the rope, so it is necessary to build in a pocket for the purpose, as shown in (*b*). In no case should the rope be bent sharply at right angles where it passes through the drum shell.

The securing of the rope to the drum or the drum shaft by several coils around each is unnecessary. With one coil around either the drum or the shaft, a pull of 1 lb. will resist a weight of 9 lb.; if two coils, a pull of 1 lb. will resist 9×9=81 lb.; if three coils, 9×9×9=729 lb., and so on, multiplying the former result by 9 for each additional coil.

**(a)**

**(b)**

FIG. 1

**Rope Sockets.**—The common method of attaching the socket shown in Fig. 2 to a rope is as follows: The rope is pushed through from the small end and is allowed to project any convenient distance. It is then firmly wrapped with wire at a point a little more than twice the depth of the socket from the end. The end of each strand is untwisted, a few of the wires cut away, and the others bent back upon themselves.

This makes the end of the rope conical, in which condition it is drawn back into the socket, and a conical wedge is rammed into the center of the hemp core to spread the wires against the side of the socket. The socket and a small length of the rope next thereto are covered with a layer of moist fireclay, and melted Babbitt metal is

FIG. 2

run into the socket, until it fills the space completely and thus cements the whole into a solid mass. This entire operation must be carefully performed, otherwise all of the wires will not be engaged, and thus an undue strain will

be thrown upon other wires or strands, possibly resulting in the failure of the rope at some distance from the socket.

The following method of attaching the socket is employed by John A. Roebling's Sons Company. As before, the rope is fitted through the socket and allowed to project. Wires are then securely served around the rope, the strands opened for a distance equal to the length of the basket of the socket, and the hemp center cut off the length of the opening. The wires are then well cleaned with kerosene and wiped dry. After the strands are separated into wires, which may be conveniently done with a small piece of pipe, the wires are placed into a solution of equal parts of water and hydrochloric acid or muriatic acid, *HCl*, for 5 min., and then are cleaned off. They are then redipped into the solution, which has been made weaker by the addition of 1 part of water (now 2 parts of water to 1 part of acid). The wires are then bunched and bound together by wire about 1 in. from the top. When the socket has been pushed over the wires until their ends are even with the top of the basket, fireclay is placed around the rope at the bottom of the socket, to serve as a shield, and melted zinc is poured into the basket of the socket. It will be noted that in this method of fastening none of the wires are cut out and none are bent back upon themselves; the rope is merely opened up, untwisted, and the ends of the wires bunched together.

Instead of using a socket, the end of the rope may be bent around a thimble and the end fastened by clamping the parts of the rope with clevices, as shown in Fig. 3 (*a*); or with iron bands that are sometimes held in place by nails, inserted between the strands, as in (*b*), though this practice is not recommended; or by wrapping the rope with wire, as in (*c*). In the last method, the end of the rope is frayed, and the loosened wires are arranged evenly around the main portion of the rope before wrapping is commenced.

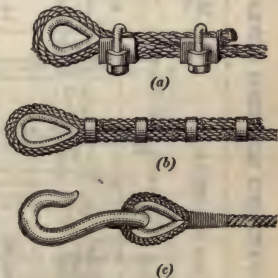

Fig. 3

## WIRE-ROPE TABLES

The accompanying tables (eleven in number) giving the ultimate strengths of wire ropes, proper size of sheaves to be used therewith, etc. are taken from the latest practice of the leading American manufacturers of wire rope. The strengths given are ultimate strengths, the working strains to which the rope is actually subjected being usually one-fifth of these; that is, a factor of safety of 5 is commonly employed, although one of 6 is not unusual, and even 10 is used, particularly in elevator work where passengers are carried. The use of these tables when selecting a hoisting rope for any particular service is best illustrated by means of an example.

EXAMPLE.—A total load of 8 T. is to be hoisted from a shaft 300 ft. deep. What size rope should be employed, allowing a factor of safety of 5?

SOLUTION.—Since the factor of safety is 5, the rope selected must have an ultimate strength of $5 \times 8 = 40$ T. Standard hoisting ropes are $6 \times 19$ and commonly of cast steel. The first table shows that a $1\frac{1}{8}$-in. rope of this kind has a breaking strength of 38 T., and one $1\frac{1}{4}$ in. in diameter, a breaking strength of 56 T. The weight of the smaller rope is 2 lb. per ft., and of the larger 2.45 lb. In the one case the weight of the rope will be $300 \times 2 = 600$ lb. $= .3$ T., and in the other $300 \times 2.45 = 735$ lb. $= .36$ T. If a $1\frac{1}{8}$-in. rope is used, the rope is called upon to sustain a load of 40.3 T.; if a $1\frac{1}{4}$-in. rope is used, the strain is 40.36 T. Therefore, the smaller rope is not quite strong enough and the larger rope is considerably over strength. Probably the $1\frac{1}{8}$-in. rope with a factor of safety a little less than 5 would answer, but better practice demands the selection of the larger rope; the factor of safety being nearly 6. The table also shows that the minimum diameter of sheave or drum for the $1\frac{1}{8}$-in. rope is 5 ft., and for the $1\frac{1}{4}$-in. rope, 6 ft.

## WIRE-ROPE CALCULATIONS

The *working load*, also called the proper working load, is the maximum load that a rope should be permitted to support under working conditions. The stress on a rope to which a load is attached, and which bends over a sheave, is made up of the load on the rope, known as the *load stress*, and the bending of the rope about a sheave or drum, known as the *bending stress*. That is, if

$S$ = total safe stress;
$S_b$ = bending stress;
$S_l$ = load stress;
$S = S_b + S_l$ and $S_l = S - S_b$.

The total stress must not equal the elastic limit of the material composing the rope and is usually taken as from one-third to one-fourth the approximate breaking stress. It is only quite recently that account has been taken of this second stress and it is not by any means universal practice to consider it when calculating the size of rope needed for a given purpose.

If a given weight is to be hoisted with a wire rope, the proper size of rope to use may be taken directly from the tables, but these do not take account of the bending stress, except by allowing for it in the factor of safety assumed.

A second method calculates the bending stress. The following formulas and the diagram based on them are given by Mr. E. T. Sederholm, former chief engineer for Fraser & Chalmers, and will be found in the hoisting-engine catalog of the Allis-Chalmers Co. The general formula for the bending stress is

$$S_b = \frac{E\,a\,A}{D};$$

in which
$S_b$ = bending stress;
$E$ = modulus of elasticity;
$a$ = diameter of each wire;
$D$ = diameter of drum or sheave, in inches;
$A$ = total area of wire cross-section, in inches.

For a rope of 19 wires to the strand the diameter of each wire is about one-fifteenth (exactly $\frac{100}{15.52}$) of the diameter of the rope. That is, if $d$ = diameter of rope, $a = \frac{d}{15.52}$; and by substituting this in the formula, $S_b = \frac{E\,A\,d}{15.52\,D}$.

The modulus of elasticity for the different kinds of wire is given different values by different authorities. Mr. Sederholm uses 29,400,000 in his formula and diagram, and Mr. Hewitt 28,500,000, the same modulus being used for the different materials of which ropes are made.

The cross-section of metal $A$ in a wire rope is approximately $.4d^2$, or it may be more accurately calculated by multiplying the cross-section of each wire, as given by a wire table, by the number of wires in the rope.

EXAMPLE.—Find the bending stress in a 19-wire, cast-steel hoisting rope 2 in. in diameter, winding on an 8-ft. drum, if $A = .4d^2$, and $E = 29,400,000$.

SOLUTION.—Applying the formula just given, the bending moment is

$$S_b = \frac{29,400,000 \times 2^3 \times .4}{10 \times 15.52 \times 96 \times 2,000} = 31.51 \text{ T.}$$

The approximate breaking stress for such a rope is 106 T., and if a factor of 3 is assumed $106 \div 3 = 35 +$ T. for the safe working stress, and $35 - 32 = 3$ T., for the safe lifting load under the given conditions.

Mr. Wm. Hewitt, of the Trenton Iron Co., has given a similar but more complicated formula for the bending stress, which is supposed to give somewhat more accurate results, as he has introduced terms that allow for the actual radius of the bend at the outside fiber of the rope, while the Sederholm formula assumes the radius of the bend to be the radius of the sheave.

Mr. Hewitt's formula is as follows:

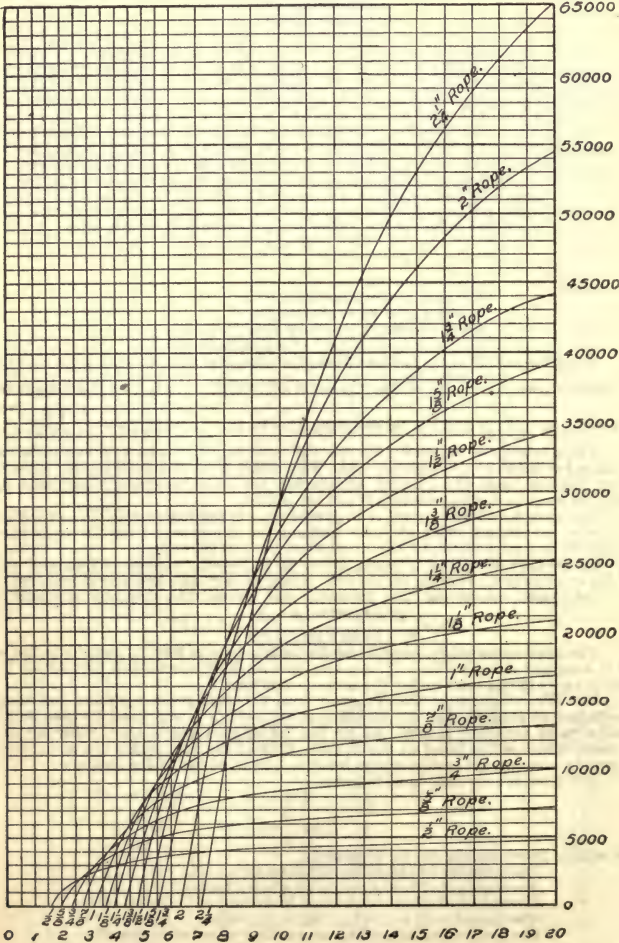
$$S_b = \frac{EA}{2.06\,\frac{R}{d} + C}$$

in which $S_b$ = bending stress, in pounds;
$E$ = modulus of elasticity (28,500,000);
$A$ = aggregate area of wires, in square inches;
$R$ = radius of drum or sheave, in inches;
$d$ = diameter of individual wires, in inches;
$C$ = a constant depending on number of wires in strands.

The values of $d$ and $C$ are:

| *7-Wire Rope* | *19-Wire Rope* |
|---|---|
| $d = \frac{1}{9}$ diameter of rope | $d = \frac{1}{15}$ diameter of rope |
| $C = 9.27$ | $C = 15.45$ |

For 12-wire and 16-wire ropes the values are intermediate in proportion to the number of wires. In the case of ropes having strands composed of different sizes of wires, take the larger of the outer layer for the value of $d$.

(*By permission of E. T. Sederholm, Chief Engr., Fraser & Chalmers, Chicago.*)


Mr. Hewitt assumes one-third of the approximate breaking stress as the maximum safe stress and uses 28,500,000 for the modulus of elasticity.

If the problem given under the Sederholm formula is worked out by the Hewitt formula the safe working load will be $11\frac{1}{2}$ T., while the table gives $106 \div 5 = 21.2$ T.

The Sederholm diagram gives for a load of 21.2 T. a sheave between 13 and 14 ft. in diameter, the formula gives a sheave of $11\frac{1}{2}$ ft. in diameter, while the table gives $9\frac{3}{4}$ ft. It is evident that there is a wide difference of opinion among the wire-rope authorities and a good opportunity for experimental work along this line.

In using the Sederholm or Hewitt formulas, there are two unknown quantities, the diameter of the rope $d$ and the diameter $D$ or radius $R$ of the drum. $d$ varies inversely as $D$, that is, for a given load, the smaller $d$ is taken the larger $D$ must be to give the same conditions of safety.

If a certain ratio between $S_b$ and $S_l$ could be assumed in the formula $S = S_b + S_l$ the problem could be easily solved, but an examination of this ratio in a number of cases where good results have been obtained from hoisting ropes shows it to vary from $\dfrac{S_l}{S_b} = 1$ to $\dfrac{S_l}{S_b} = \dfrac{2}{5}$. In the transmission of power by wire ropes, Mr. Hewitt assumes $\dfrac{S_l}{S_b} = \dfrac{1}{2}$, but this relation will scarcely hold in a hoisting problem, and the foregoing problem must be solved by the cut-and-try method.

**Proper Working Load.**—For steel hoisting ropes, made with 19 wires to the strand, when used on drums of different diameters, the proper working load may be found from the following formula, in which the total strain on the rope, including bending strain and the strain due to load is assumed at 50,000 lb. per sq. in. of actual steel section.

Let
$d$ = diameter of rope, in inches;
$D$ = diameter of drum, in inches;
$S$ = strain per square inch due to bending;
$L$ = proper working load, in pounds.

$$S = 1,894,000 \times \frac{d}{D}$$

$$L = 20,000d^2 - 757,600 \times \frac{d^3}{D}$$

**Starting Stress on Hoisting Rope.**—When selecting a hoisting rope, due allowance must be made for the shock and extra stress imposed on the rope when the load is started from rest. Experiments made by placing a dynamometer between the rope and the cage have shown that the starting stress may be from two to three times the actual load. The experiments referred to were made in England and are here given; the tons are those of 2,240 lb., and the hundredweights (cwt.), 112 lb.

## STRESS OF ROPE ON PLANES

| Rise per 100 Ft. Horizontal Feet | Angle of Inclination | Stress per Ton of 2,000 Lb. Pounds | Rise per 100 Ft. Horizontal Feet | Angle of Inclination | Stress per Ton of 2,000 Lb. Pounds |

**Stress in Hoisting Ropes on Inclined Planes of Various Degrees.**—The preceding table is based on an allowance of 40 lb. per T. for rolling friction, but there will be an additional stress due to that portion of the weight of the rope which acts vertically.

**Relative Effect of Various Sized Sheaves or Drums on Life of Wire Ropes.** Mine officials and other users of wire ropes have often felt the want of a table or set of tables that would enable them to determine at a glance what effect the use of various sized sheaves would have on various sized ropes. The following tables have been specially prepared for the Coal and Metal Miner's Pocketbook by Mr. Thomas E. Hughes, of Pittsburg, Pennsylvania. The cast-steel ropes for inclines are made of 6 strands of 7 wires each, laid around a hemp core, the cast-steel hoisting ropes are made of 6 strands of 19 wires each, laid a hemp core; and the iron hoisting ropes, of 6 strands of 19 wires each, laid around a hemp core.

## CAST-STEEL ROPES FOR INCLINES

| Diameter of Rope. Inches | Percentages of Life for Various Diameters | | | | | | |
|---|---|---|---|---|---|---|---|
| | 100 | 90 | 80 | 75 | 60 | 50 | 25 |
| | Diameters of Sheaves or Drums in Feet | | | | | | |

## CARE OF WIRE ROPES

**Ordinary Method of Splicing Wire Rope.**—The tools required for splicing wire ropes by the ordinary method are a pair of iron nippers for cutting off strands; two marline spikes, one round and one oval, for opening strands; one knife to cut hemp center; two clamps to untwist rope to insert ends of strands or, in place of them, two short hemp-rope slings, with a stick for each as a lever; a wooden mallet and some rope twine. Also, a bench and vise are handy.

The length of the splice depends on the size of the rope. The larger ropes require the longer splices. The splice of ropes from $\frac{3}{8}$ in. to $\frac{3}{4}$ in. in diameter should not be less than 20 ft.; from $\frac{3}{4}$ in. to $1\frac{1}{8}$ in., 30 ft.; and from $1\frac{1}{8}$ in. up, 40 ft.

To splice a rope, tie each end with a piece of cord at a distance equal to one-half the length of the splice, or 10 ft. back from the end for a $\frac{3}{8}$-in. rope, after which unlay each end as far as the cord. Then cut out the hemp center, and bring the two ends together as close as possible, placing the strands of the one end between those of the other, as shown in Fig. 1 (*a*). Now remove the cord *k* from the end *M* of the rope, and unlay any strand, as *a*, and follow it up with the strand of the other end *M'* of the rope that corresponds to it, as *a'*. About 6 in. of *a* is left out, and *a'* is cut off about 6 in. from the rope, thus leaving two short ends, as shown at *P* in (*b*), which must be tied for the present by cords as shown. Wind the cord *k* again around the end *M* of the rope, to prevent the unraveling of the strands; after which remove the cord *k'* on the other or *M'* end of the rope, and unlay the strand *b*; follow it up, as before, with the strand *b'*, leaving the ends out, and tying them down for the present, as described in the case of strands *a* and *a'*, see *O*; also, replace the cord *k'*. Again remove the cord *k* and unlay the next strand, as *c*, and follow it up with *c'*, stopping, however, this time within 4 ft. of the first set. Con-

tinue this operation with the remaining six strands, stopping 4 ft. short of the preceding set each time. The strands are now in their proper places, with the ends passing each other at intervals of 4 ft., as shown in (c). To dispose of the loose ends, clamp the rope in a vise at the left of the strands *a* and *a'*,

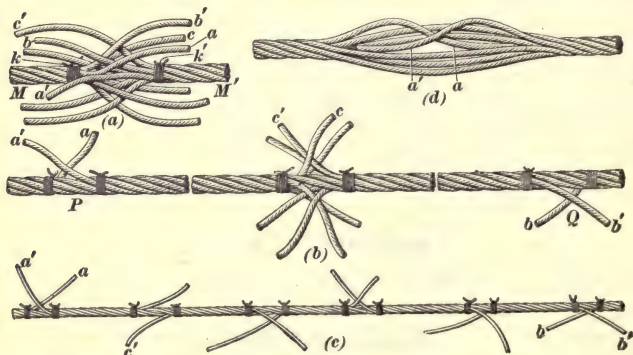

FIG. 1

view (c), and fasten a clamp to the rope at the right of these strands; then remove the cords tied around the rope that hold these two strands down; after which turn the clamp in the opposite direction to which the rope is twisted, thereby untwisting the rope, as shown in (d). The rope should be untwisted enough to allow its hemp core to be pulled out with a pair of nippers. Cut off 24 in. of the hemp cores, 12 in. at each side from the point of intersection of the strands *a* and *a'*, and push the ends of the strands in their place as shown in (d). Then allow the rope to twist up to its natural shape, and remove the clamps. After the rope has been allowed to twist up, the strands tucked in generally bulge out somewhat. This bulging may be reduced by lightly tapping the bulged part of the strands with a wooden

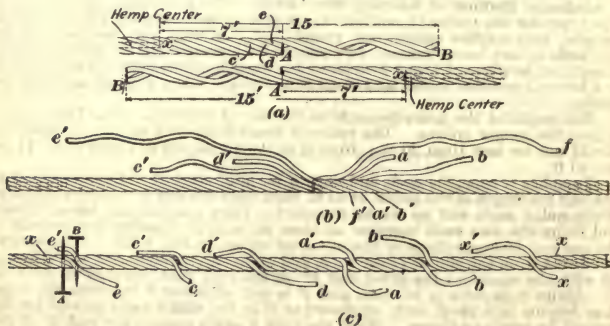

FIG. 2

mallet, which will force their ends farther into the rope. Proceed in the same manner to tuck in the other ends of the strands.

**Rapid Method of Splicing Wire Rope.**—The only tools needed in the rapid method of splicing wire ropes are a cold chisel and hammer for cutting

and trimming the strands, and two needles 12 in. long, made of good steel and tapered ovally to a point. Cut off the ends of the ropes to be spliced and unlay three adjacent strands of each back 15 ft.; cut out the hemp center to this point and relay the strands for 7 ft. and cut them off. Pull the ropes by each other until they have the position shown in Fig. 2, (a), cut off a and d', b and c', view (b), making their lengths approximately 10 and 12½ ft., respectively, measured from the point where the hemp centers were cut. Place the ropes together, unlay e, d, c, Fig. 2, view (a), keeping the strands together, and follow with e', d', c', (b). Similarly, unlay f', a', b', and follow with f, a, b, until the rope appears as in (c). Next run the strands into the middle of the rope. To do this, cut off the end of the strand e', so that when it is put in place it will just reach to the end x of the hemp core, and then push the needle A, through the rope from the under side, leaving two strands at the front of the needle, as shown. Push the needle B through from the upper side and as close to the needle A as possible, leaving the strands e and e' between them; place the needle A on the knee and turn the needle B around with the coil of the rope, and force the strand e' into the center of the rope. Repeat this operation with the other ends and cut them off so that the ends coming together in the center of the rope will butt against each other as nearly as possible.

**Wear of Wire Ropes.**—The deterioration of wire ropes may be either external or internal, and may be due (1) to abrasion, due to the rubbing of the outside surface of the rope against other objects, or to the internal chafing of the wires composing the strands against one another; (2) to injury from overloading, to shock due to sudden starting of the load, or to repeated bendings about too sharp angles or over sheaves or rollers of too small a diameter for the size of the rope; (3) to rust or corrosion of the wire from acid waters, or to decay of the hemp cores.

As a result of abrasion, the wires in a rope are either flattened or torn apart. With properly designed drums and head-frame and properly placed sheaves, a hoisting rope is but slightly abraded, and the wear is due chiefly to bending or to overloading. A haulage rope is subjected to constant abrasion in passing over rollers and sheaves and from dragging along the bottom and sides of the haulage ways and from the grips. It is also often subject to severe shocks and abrasion from the lashing or vibration when the winding engine starts.

The wear and tear on a rope increases as its velocity is increased; hence, conditions permitting, it is better to increase the output by increasing the load within allowable limits rather than by increasing the velocity of the rope.

**Inspection of Ropes.**—The life of a hoisting rope depends not only on its quality, but also on the conditions under which it is used and on the carefulness of the engineer in handling the load. A rope should be inspected often and at regular intervals; at some mines, the hoisting ropes are inspected every morning before lowering the men. The cage is slowly lowered and then raised, each rope being carefully examined by an inspector to detect any broken wires. Particular attention should be given to the part of the rope where it is attached to the socket at the cage, as this part is more subject to corrosion and sharp bending than any other. When the core fails at any point the rope should be discarded at once as the wires are likely to kink and break internally as the rope passes over the sheave. At some mines, hoisting ropes are discarded at regular intervals, whether they show wear or not. Haulage ropes do not require as frequent examination and are not discarded as quickly as hoisting ropes, as much less in the way of life and property is dependent on them. If a new piece of loose hemp rope is given one turn around the haulage rope and each end held firmly while the rope is run the presence of loose wire ends will be shown.

**Lubrication of Wire Ropes.**—Mine water has a very corrosive action on wire ropes, and a rope will soon be destroyed unless the water is prevented from coming in contact with the metal. For this reason, black oil or some lubricating preparation is applied to the rope, but any lubricant used must be free from acids or other substances that will corrode the wire.

For hoisting ropes, 1 bu. of freshly slaked lime to 1 bbl. of pine or coal tar makes a good lubricant; with pine tar, which contains no acid, tallow may be used instead of lime. Another mixture contains tar, summer oil, axle grease, and a little pulverized mica, mixed to such a consistency that it will penetrate thoroughly between the wires and will not dry or strip off. The lubricant should not be thick enough to render difficult the thorough inspection of the rope, and all lubricants of this nature should be used sparingly after the first application, as the rope should be kept clean and free from grit. Graphite is also used for the purpose.

Lubricants may be applied by running the engine slowly and allowing the rope to pass through a bunch of waste saturated with lubricant; by rubbing the lubricant into the rope by means of a brush; or by pouring the oil into the groove of the sheave as the rope is run slowly back and forth. A new hoisting rope should be passed through a bath of hot lubricant and thus be thoroughly lubricated.

Haulage ropes are not usually lubricated as thoroughly as hoisting ropes on account of the grease causing slipping of grips and gathering of dirt and dust, but they can be treated with raw linseed oil thickened with lamp-black boiled with an equal portion of pine tar, and the mixture applied while hot. Ordinary black oil, such as is used to oil mine cars and hoisting ropes, can be used on haulage ropes where no friction grips are employed. These mixtures, if fluid, can be poured on the rope as it is run over the sheave, or applied from a leather-lined box filled with oil. Patent lubricants known as *cable shields* or *rope fillers*, which fill the interstices between the strands, are often used on tail and main ropes.

**General Precautions.**—Wire rope is as pliable as new hemp rope of the same strength; the former will therefore run on the same sized sheaves and pulleys as the latter. But the greater the diameter of the sheaves, pulleys, and drums, the longer wire rope will last. In the construction of machinery for wire rope, it will be found good economy to make the drums and sheaves as large as possible.

The tables of wire-rope manufacturers give proper diameters of drum or sheave at from 50 to 65 times the rope diameter; but the expression should more properly be the minimum admissible diameter. For ordinary service, by using sheaves and drums from 75 to 100 times the diameter of the rope, the average life of hoisting ropes will be materially lengthened. For rapid hoisting, during which abnormal strains are most likely to occur, or where a low factor of safety is employed, a sheave diameter of 150 times that of the rope is to be recommended.

Experience has demonstrated that the wear increases with the speed; it is therefore better to increase the load than the speed. Wire rope is manufactured either with a wire or a hemp center; the latter is more pliable than the former, and will wear better where there is short bending.

Wire rope must not be coiled or uncoiled like hemp rope. When mounted on a reel, the reel should be mounted on a spindle or flat turntable to pay off the rope. When shipped in a small coil, without reel, the coil should be rolled over the ground like a wheel, and the rope run off in that way. All untwisting or kinking must be avoided.

A rope should not be changed from a large drum to a small one, for it will not work so well, neither will it last as long. This is also true, but in a lesser degree, of ropes changed from a small drum to a large one. After having been used for some time on a drum, the rope adapts itself to that diameter and resents a change. Rope sheaves should be made to fit the rope, and should be filled in with well-seasoned blocks of oak or other hardwood, set on end; this will save the rope and increase adhesion.

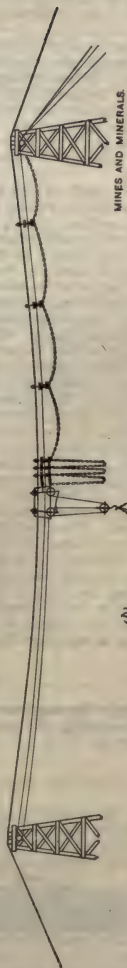
---

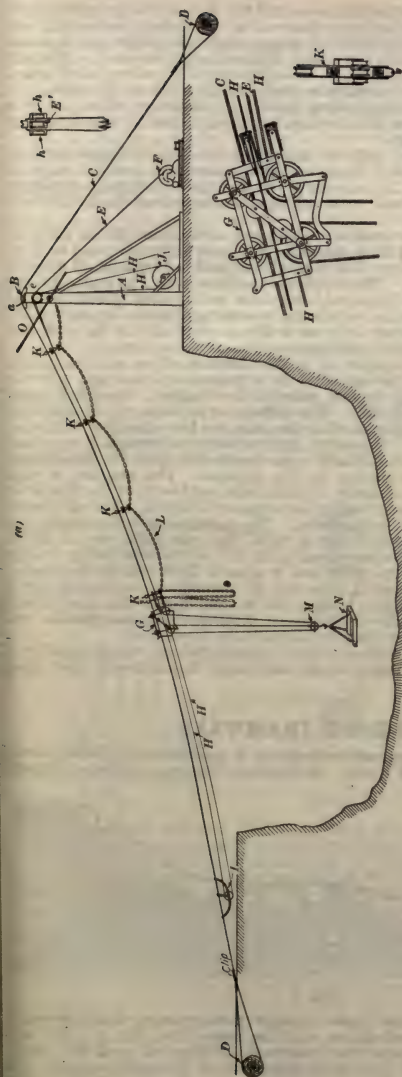
# CABLEWAYS AND TRAMWAYS

**Cableways.**—A suspension cableway is a hoisting and conveying device using a suspended cable for a trackway. There are two types: the inclined, or semi-gravity, Fig. 1, and the horizontal, Fig. 2.

The *inclined cableway* consists of a cable inclined 20° to 22° to the horizontal, and passing over a cast-iron saddle *B* on top of a tower or frame *A*. It is anchored by logs *D* buried about 5 ft. underground, or from iron plugs secured in the rock, when the rock is near the surface. The trolley carriage *G* runs down the incline of the cableway by gravity until it reaches a stop. A hoisting rope *E* operated by a winding drum *F* leads over a sheave pulley *e*, thence to a pulley in the carriage *G*, thence to a fall block *M*, upwards again to a second pulley in the carriage, and downwards again to the fall block. Winding in the rope hoists the fall block to the carriage, the carriage remaining at the lower stop. When the fall block collides with the carriage, both the carriage and the fall block are pulled up the incline cable, and when the carriage arrives at the head-tower, a gate, or hook, *O* is lowered to hold it in place. The fall block is then lowered and the load discharged. The engine *F* has usually a $10'' \times 12''$ double cylinder and a single friction drum 37 in. in diameter.

FIG. 1

FIG. 2




MINES AND MINERALS.

An endless rope $H$ takes several turns around the sheave $J$ to prevent it from slipping, and both ends are passed over sheaves at the top of the derrick, one end being secured to the front of the carriage, while the other end is taken through the carriage and around the return sheave $I$ and fastened to the rear end of the carriage $G$. The endless-rope wheel $J$ is provided with a band brake, which, when applied, holds the carriage securely at any point on the cable.

All ropes pass through the supporting trolleys $K$, which are connected by a chain $L$. These trolleys follow the carriage by gravity, and the chain may or may not be fast to the carriage.

Instead of chain-connected trolleys, patent button-stop, fall-rope carriers, which are lighter, may be used. These are spaced along an auxiliary rope on which buttons are screwed. The carriers are picked up by a horn on the front of the carriage. These are said to be cheaper for operation than the chain trolleys.

The length of the span for inclined cableways varies from 200 to 1,200 ft. The main rope is from $1\frac{1}{2}$ to $2\frac{1}{4}$ in. in diameter, the hoisting rope from $\frac{5}{8}$ to $\frac{3}{4}$ in., and the endless rope $\frac{7}{16}$ and $\frac{1}{2}$ in. The rope mostly used is 6 strands, 19 wires to the strand, crucible cast steel. The hoisting rope lasts from 1 to 2 yr., and the main cable from 5 to 10 yr. These cableways are widely used about the slate quarries in Eastern Pennsylvania, where the operating expense for each cable, where two or more are connected with one boiler, is about $5 per da. of 10 hr.; this includes the engineer, steam, and maintenance of the cableway.

The *horizontal cableway* requires a double friction drum and reversible link-motion engine. It may be operated at any inclination of the carrying cable and either from the high or low point of the support, though, if possible, it should be from the higher end. The endless, or traction, rope is attached to one of the drums of the engine so that the engineer has complete control of the carriage; hence, because of its greater applicability, this system is supplanting the inclined, although the inclined costs one-fourth less for installation. The method of operation is similar to the inclined. The amount of rope required is the same in each system. A horizontal cableway of the Hamilton Coal Co., near Tarentum, Pennsylvania, has a span of 2,200 ft. The stationary rope is 2,500 ft. long and $2\frac{1}{4}$ in. in diameter. The hoisting rope is 4,500 ft. long and $\frac{5}{8}$ in. in diameter. The head-tower is 80 ft. high, the tail-tower is 100 ft. and the rope deflects 80 ft. The skip used holds 3 T. of coal and makes 10 trips per hour. Five men operate the plant and it takes 2 T. of coal for the engine. Based on a capacity of 100 T. per da., the cost of carrying the coal is 13c. per T. For a cableway of average length, 1,000–1,500 ft., the cost of operation should not be one-half the above cost. A cableway, 2,140 ft. long was used in constructing the dam at the power plant at Glens Falls, New York.

One or both towers of a cableway may be mounted on wheels capable of moving on a track at right angles to the cable and the cableway then made to cover a wide territory.

## WIRE-ROPE TRAMWAYS

**Single Tramways.**—A tramway, in America, is a cableway of the horizontal type consisting of a number of spans. In England, the term cableway includes tramways.

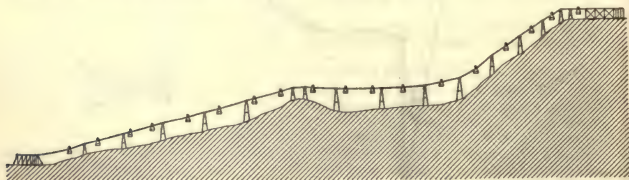


FIG. 1

Single wire-rope tramways have a single moving rope, which serves to support and advance the load at one and the same time, Fig. 1. This rope passes over suitable sheaves at the intermediate supports, and the load is carried in buckets suspended from it by gooseneck or straight hangers. The hangers are usually attached to the cable by means of a clip, which is either

inserted in the center of the cable or strapped to it. The carriers are often loaded and unloaded while in motion, the loading being accomplished by a traveling mechanical hopper and the unloading by a drop bottom to the bucket. If the line is level, or the grade light, the hangers are provided with box heads filled with wood or leather and rubber, which rest on the rope; the rubber or wood providing sufficient friction to prevent the hangers' slipping. With this system, long spans are evidently out of the question, because with a long span the angle of the rope in the vertical plane, at the supports, becomes so great that the friction will not hold the box head. For all practical purposes, grades exceeding 1 : 4 are to be avoided; and for steeper grades, to prevent slipping, a clamp or a clip inserted in the rope is used to fasten the hanger to the rope.

The single-moving rope tramways carry loads not exceeding 200 lb. The speed of the rope for the variety in which the loads are fastened to the rope may be as high as 450 ft. per min., and for one in which the hanger is loose, 200 ft. per min. The single moving-rope tramway has a capacity up to 200 T. per da., and may be built, say, $1\frac{1}{2}$ to 2 mi. long.

**Double Tramways.**—The more satisfactory and substantial kind of wire-rope tramway has one or more fixed ropes, which constitute the permanent way, and an endless traction rope. The loaded carrier travels outwards on one fixed cable and returns by a parallel one suspended from the opposite side of the same supports. The terminals have suitable appliances for loading and unloading the buckets, either by hand or automatically.

The intermediate supports are built of wood or steel framing, with saddles of cast iron $a$, Fig. 2 in which the fixed cables $b$ rest. The traction rope $c$ is supported (in the absence of a bucket) by the rollers $d$, set conveniently on the supports. The load is carried in buckets $e$, or other contrivances suitable for the purpose, which are suspended from a trolly $f$, which runs on the fixed cables, the wheels of which are large enough to pass over the rope couplings, and

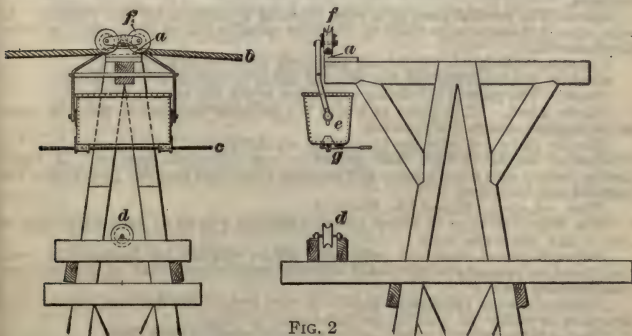

Fig. 2

also to clear the saddles. Grips $g$ attach the carriers to the traction rope. These grips may be operated by hand or automatically.

This kind of tramway is capable of carrying individual loads up to 1,400 or 1,500 lb., not including the weights of the bucket and hanger itself. The speed of traction rope may be from 150 to 350 ft. per min. The capacity is from 200 to 1,000 T. per da. of 10 hr. These figures represent good, safe, practice, but they are not, of course, inflexible.

The maximum length of line that may be built in one section varies largely with conditions of load, spacing of supports, contour of ground, etc. Wire-rope tramways work under great difficulties, and probably $2\frac{1}{2}$ to 4 mi. is the economical limit. This has been exceeded, but for a much greater distance the friction becomes too great for economical working of the traction rope. This does not, however, limit the length of tramway which may be built, as the power station may be located at a convenient intermediate point, dividing the line into sections. Several intermediate power stations may be used, and the length of the line greatly increased above the limit given. A tramway at Grand Encampment, Wyoming, is 16 mi. long and carries 40 T. of ore each hour.

# GLOSSARY OF ROPE TERMS

*Annealed Wire Rope.*—A wire rope made from wires that have been softened by annealing and the tensile strength thereby lowered.

*Bending Stress.*—The stress produced in the outer fibers of a rope by bending over a sheave or drum.

*Breaking Strain, Breaking Strength, Breaking Stress.*—The least load that will break a rope. These terms are used indiscriminately to mean the load that will break a rope. The stress on a rope at the moment of breaking is the *breaking stress,* and the strain or deformation produced in the material by this stress is the breaking strain.

*Bright Rope.*—Rope of any construction, whose wires have not been galvanized, tinned, or otherwise coated.

*Cable-Laid Rope.*—Wire cables made of several ropes twisted together, each rope being composed of strands twisted together without limitation as to the number of strands or direction of twist. A fiber cable-laid rope is a rope having three strands of hawser-laid rope, twisted right-handed.

*Cable.*—Same as cable-laid rope; a fiber cable consists of three hawsers laid up left-handed.

*Cast Steel.*—Steel that has been melted, cast into ingots, and rolled out into bars.

*Clamp.*—A device for holding two pieces or parts of rope together by pressure.

*Clip.*—A device similar to a clamp but smaller and for the same purpose.

*Coir.*—Cocoanut-husk fiber.

*Compound.*—A lubricant applied to the inside and outside of ropes preventing corrosion and lessening abrasion of the rope when in contact with hard surfaces.

*Core.*—The central part of a rope forming a cushion for the strands. In wire ropes it is sometimes made of wire, but usually it is of hemp, jute, or some like material.

*Coupling.*—A device for joining two rope ends without splicing.

*Crucible Steel.*—A fine quality of steel made by the crucible process.

*Drum.*—The part of a hoisting engine on which the rope is wound.

*Elastic Limit.*—That point at which the deformations in the material cease to be proportional to the stresses.

*Elevator Rope.*—A rope use to operate an elevator.

*Endless Rope.*—A rope that moves in one direction, one part of which carries loaded cars from a mine at the same time that another part brings the empties into the mine.

*Fiber.*—A single thread-like filament.

*Flat Rope.*—A rope in which the strands are woven or sewed together to form a flat, braid-like rope.

*Flattened-Strand Rope.*—A wire rope whose strands are flattened or oval. and therefore presents an increased wearing surface over that of the ordinary round-strand rope.

*Flattened-Strand Triangular Rope.*—A wire rope of the flattened-strand construction in which the strands are triangular in shape.

*Fleet.*—Movement of a rope sidewise when winding on a drum.

*Fleet Wheel.*—A grooved wheel or sheave that serves as a drum and about which one or more coils of a haulage rope pass.

*Galvanized Rope.*—Rope made of wires that have been galvanized or coated with zinc to protect them from corrosion.

*Grip Wheel.*—A wheel, the periphery of which is fitted with a series of togglejointed, cast-steel jaws that grip the rope automatically.

*Guy.*—A strand or rope used to support a pole, structure, derrick, or chimney, etc.

*Haulage Rope.*—A rope used for haulage purposes.

*Hawser.*—Any wire rope used for towing on lake or sea. A fiber hawser consists of three strands laid up right-handed.

*Hawser-Laid Rope* has three strands of yarn twisted left-handed, the yarns being laid up right-handed. Synonymous with cable-laid rope as applied to wire ropes.

*Hawser Wire Rope.*—Galvanized rope of iron or steel, usually composed of 6 strands, 12 wires each, principally used in marine work for towing purposes.

*Hemp.*—A tough, strong fiber obtained from the hemp plant.

*Hoisting Rope.*—A rope composed of a sufficient number of wires and strands to insure flexibility. Such ropes are used in shafts, elevators, quarries, etc.

*Idler.*—A sheave or pulley running loose on a shaft to guide or support a rope.

*Jute.*—A fiber obtained from the inner bark of two Asiatic herbs: *Corchorus capsularis* and *C. olitorius.*

*Lang Lay Rope.*—A rope in which the wires in each strand are twisted in the same direction as the strands in the rope.

*Lay.*—The direction, or length, of twist of the wires and strands in a rope.

*Live Load.*—A load that is variable in distinction from a constant load.

*Load Stress.*—The stress produced by the load.

*Locked-Wire Rope.*—A rope with a smooth cylindrical surface, the outer wires of which are drawn to such shape that each one interlocks with the other and the wires are disposed in concentric layers about a wire core instead of in strands. Particularly adapted for haulage and rope-transmission purposes.

*Manila.*—The fiber of *Musa textilis;* Manila hemp.

*Modulus of Elasticity.*—The ratio between the amount of extension or compression of a material and the load producing this same extension or compression.

*Plow Steel.*—A select grade of steel of high tensile strength; first used in rope for plowing fields.

*Proper Working Load.*—The maximum load that a rope should be permitted to support under working conditions. (See *working load.*)

*Regular-Lay Rope.*—A rope in which the wires in each strand are twisted in opposite direction to the strands in the rope.

*Round-Strand Rope.*—A rope made of round twisted strands.

*Running Rope.*—A flexible rope that will pass through blocks and used for hoisting on shipboard. The term is also often used for any moving rope.

*Sheave.*—A wheel or pulley around or over which a rope passes.

*Shroud Laid,* or *Four-Strand, Rope* has four strands laid around a core.

*Sisal.*—A hemp; the fiber of the *Agave Sisalona.*

*Socket.*—A device fastened to the end of a rope by means of which the rope may be attached to its load; the socket may be opened or closed.

*Splice.*—The joining of two ends of rope by interweaving the strands.

*Step Socket.*—A special form of socket for use on locked-wire rope.

*Stirrup.*—An adjustable bale of a socket.

*Stone Wire.*—Wire smaller than No. 14 put up in 12-lb. coils, which are about 8 in. inside diameter.

*Strand.*—A varying number of wires or fibers twisted together; the strands in turn are twisted together, forming a rope.

*Stress.*—A force or combination of forces tending to change the shape of a body.

*Strain.*—A change of shape produced in a body. (Stress and strain are often used incorrectly as synonymous terms.)

*Surging.*—The flapping of a moving rope.

*Swedish Iron.*—A soft and comparatively pure iron.

*Switch Rope.*—A short length of rope fitted with a hook on one end and a link on the other, used for the switching of freight cars.

*Tail-Rope.*—(1) The rope that is used to draw the empties back into a mine in a tail-rope haulage system. (2) A rope attached beneath the cage when the cages are hoisted in balance.

*Taper Rope.*—A rope that has a gradually diminishing diameter from the upper to the lower end. The diameter of the rope is decreased by dropping one wire at a time at regular intervals. Both round and flat ropes may be made tapered, and such ropes are intended for deep-shaft hoisting with a view to proportioning the diameter of the rope to the load to be sustained at different depths.

*Tensile Strength.*—The stress required to break a rope by pulling it in two.

*Thimble.*—An oval iron ring around which a rope end is bent and fastened to form an eye.

*Tiller Rope.*—A very flexible wire rope composed of six small ropes, usually of seven-wire strands laid about a hemp core.

*Tinned Rope.*—Rope made of wires that have been coated with tin to protect them from corrosion.

*Torsion.*—The process of twisting a wire, thereby showing its ductility.

*Traction Rope.*—A rope used for transmitting the power in a wire-rope tramway and to which the buckets are attached.

*Transmission Rope.*—A rope used for transmitting power.

*Traveler.*—A truck rolling along a suspended rope for supporting a load to be transported.

*Turnbuckle.*—A form of coupling so threaded or swiveled that by turning it the tension of a rope or rod may be regulated.

*Ultimate Tensile Strength.*—Same as tensile strength.

*Universal Lay.*—Another term for lang lay.

*Whipping.*—The flopping of a moving rope.

*Wire Gauge.*—Standard sizes or diameters for wire.

*Wire Rope.*—A rope whose strands are made of wires, twisted or woven together.

*Working Load.*—The maximum load that a rope can carry under the conditions of working without danger of straining. (Same as *proper working load.*)

*Wrought Iron.*—A comparatively pure and malleable iron.

*Yarn.*—Twisted fiber of which rope strands are made.

---

# POWER TRANSMISSION

## TRANSMISSION BY WIRE ROPES

The term transmission, as here used, applies simply to the modification of belt driving, using grooved wheels or sheaves at each end of the line. The power is applied to one sheave and taken off from the other. The friction between rope and sheaves depends directly on the weight and tension of the rope and on the nature of the surfaces in contact. This pressure is better obtained by using a large, heavy rope at a low tension than by using a smaller rope at a high tension. The deflection, or sag, of the rope, between the sheaves, is the same for both upper and lower parts of the rope when the transmission is not running and should be, according to John A. Roebling's Sons Co., equal to about $\frac{1}{30}$ of the span. The deflection may be calculated by the formula from the Trenton Iron Co.:

$$h = \frac{ws^2}{8t},$$

in which
$h$ = deflection, in feet;
$w$ = weight of rope per foot, in pounds;
$s$ = span, in feet;
$t$ = tension, in pounds.

When driving from the under side, this part of the rope will be tightened and its deflection decreased, while the upper part of the rope becomes slackened and its deflection increased. Under proper conditions, the deflection of the lower rope should be about $\frac{1}{40}$, and that of the upper about $\frac{1}{24}$ of the span. The difference in the tensions of the two parts of the rope is the effective pull of the driving sheaves, enabling power to be transmitted.

Transmission ropes are subject to three stresses: (1) The direct tension, due to the power transmitted, plus the friction and weight of the rope; (2) the bending stress, due to the bending of the rope around the sheaves; (3) the centrifugal tension, due to the centrifugal force in the rapidly running rope.

The following data on stresses in transmission ropes are given by Mr. Wm. Hewitt, of the Trenton Iron Co.: When transmitting power by wire rope, working tension should not exceed the difference between the maximum safe stress and the bending stress. It may be greater, therefore, as the bending stress is less, but to avoid slipping, a certain ratio must exist between the tensions in taut and slack portions of the rope when running, which is determined by the formula $T = Se^{fn\pi}$;

in which $T$ = tension in taut portion of rope;
$S$ = tension in slack portion;
$e$ = base of Naperian system of logarithms = 2.7182818;
$n$ = number of half laps of rope about sheaves or drums at either end of line;
$\pi$ = 3.1416;
$f$ = coefficient of friction depending on kind of filling in grooves of sheaves, or character of material on which rope tracks.

The useful effort of transmitting force is the difference between the tension of the taut and slack portions of the rope, $T - S = S(e^{fn\pi} - 1)$, and to obtain this, the initial tension, or tension when the rope is at rest, must be one-half the sum of the two tensions.

$$T + S = S(e^{fn\pi} + 1) = \frac{e^{fn\pi} + 1}{e^{fn\pi} - 1}(T - S)$$

The following are some of the values of $f$:

| | |
|---|---|
| Dry rope on a grooved iron drum | .120 |
| Wet rope on a grooved iron drum | .085 |
| Greasy rope on a grooved iron drum | .070 |
| Dry rope on wood-filled sheaves | .235 |
| Wet rope on wood-filled sheaves | .170 |
| Greasy rope on wood-filled sheaves | .140 |
| Dry rope on rubber and leather filling | .495 |
| Wet rope on rubber and leather filling | .400 |
| Greasy rope on rubber and leather filling | .205 |

The values of the coefficients corresponding to the foregoing values of $f$, for one up to six half laps of the rope, are given in the accompanying table.

## VALUE OF COEFFICIENTS

| $f=$ | $n=$ Number of Half Laps About Sheaves or Drums at Either End of Line | | | | | |
|---|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 5 | 6 |
| | Values of $e^{fn\pi}$ | | | | | |
| .070 | 1.246 | 1.552 | 1.934 | 2.410 | 3.003 | 3.741 |
| .085 | 1.306 | 1.706 | 2.228 | 2.910 | 3.801 | 4.964 |

For a given diameter of sheave, and a variable diameter of wire, a ratio exists between these diameters corresponding to a maximum working tension. This ratio results, approximately, in a working tension of one-third and a bending stress of two-thirds of the maximum safe tension, which is from one-third to two-fifths of the ultimate stress, and practically determines the minimum diameter of sheave for any rope. The ratio for any size of wire varies slightly, according to the number of wires composing the rope, and in terms of rope diameter is,

|  | *Steel* | *Iron* |
|---|---|---|
| For  7-wire rope..................... | 79.6 | 160.5 |
| For 12-wire rope..................... | 59.3 | 120.0 |
| For 19-wire rope..................... | 47.2 | 95.8 |

from which the following table is derived.

### MINIMUM DIAMETERS OF SHEAVES

| Diameter of Rope Inch | Steel Rope | | | Iron Rope | | |
|---|---|---|---|---|---|---|
| | 7-Wire | 12-Wire | 19-Wire | 7-Wire | 12-Wire | 19-Wire |
| | Diameter of Sheaves, in Inches | | | | | |
| $\frac{1}{4}$ | 20 | 15 | 12 | 40 | 30 | 24 |
| $\frac{5}{16}$ | 25 | 19 | 15 | 50 | 38 | 30 |
| $\frac{3}{8}$ | 30 | 22 | 18 | 60 | 45 | 36 |
| $\frac{7}{16}$ | 35 | 26 | 21 | 70 | 53 | 42 |
| $\frac{1}{2}$ | 40 | 30 | 24 | 80 | 60 | 48 |
| $\frac{9}{16}$ | 45 | 33 | 27 | 90 | 68 | 54 |
| $\frac{5}{8}$ | 50 | 37 | 30 | 100 | 75 | 60 |
| $1\frac{1}{8}$ | 55 | 41 | 32 | 110 | 83 | 66 |
| $\frac{3}{4}$ | 60 | 44 | 35 | 120 | 90 | 72 |
| $\frac{7}{8}$ | 70 | 52 | 41 | 140 | 105 | 84 |
| 1 | 80 | 59 | 47 | 160 | 120 | 96 |

**Sheaves.**—To decrease the bending stresses, the sheaves for wire-rope transmissions are generally of as large diameter as is practicable to give the required speed to the rope. Large sheaves are also advantageous because with them the rope is run at a high velocity allowing of a lower tension, and permitting a rope of smaller diameter to be used than would be possible with smaller sheaves, provided, of course, that the span is of sufficient length to give the necessary weight.

Sheaves are generally made of cast iron when not exceeding 12 ft. in diameter; when larger than this, they are usually built up with wrought-iron arms. Sheaves, upon which the rope is to make but a single half-turn, are made with **V**-shaped grooves in their circumference. The bottom part of the groove is widened to receive the filling, which consists of some substance to give a bed for the rope to run on and protect it from wear, and to increase the friction so that the rope will not slip. This filling is made of blocks of wood, rubber, leather, or other material. Rubber and leather have been used separately, but blocks of rubber separated by pieces of leather have been found to give the best results.

**Power Transmitted.**—The horsepower transmitted is equal to the resistance overcome (the effective pull), in pounds, multiplied by the speed of the rope, in feet per minute, and divided by 33,000 that is (formula from John A. Roebling's Sons Co.),

$$H = \frac{TV}{33,000}$$

in which $H$ = horsepower transmitted;

$T$ = difference in tension between driving and driven sides of rope;

$V$ = speed of rope, in feet per minute.

When applying this formula, $V$ is either given or assumed. $T$ is equal to the weight of the rope suspended between the sheaves multiplied by 3 (for the proportion of deflection stated).

To transmit a given horsepower, the speed of the rope may be increased and the tension (effective pull) correspondingly decreased, and a smaller rope may be used provided other considerations will allow it.

For determining the horsepower that can be transmitted over a given transmission, the following formula is given by the Trenton Iron Co.:

$$H = [cd^2 - .000006\,(W + g' + g'')]s$$

in which $H$ = horsepower that can be transmitted;

 $c$ = constant, depending on material of rope, filling in grooves of sheaves, and number of half laps about sheaves or drums at either end of line;

 $d$ = diameter of rope, in inches;

 $W$ = weight of rope, in pounds;

 $g'$ = weight of terminal sheaves and shafts;

 $g''$ = weight of intermediate sheaves and shafts.

The accompanying table gives the value of $c$ for ropes on different materials.

### TABLE OF CONSTANTS FOR ROPES ON DIFFERENT MATERIALS

| $c$ = for Steel Rope on | Number of Half Laps About Sheaves or Drums at Either End of Line | | | | | |
|---|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 5 | 6 |
| | Value of $c$ | | | | | |
| Iron............... | 5.61 | 8.81 | 10.62 | 11.65 | 12.16 | 12.56 |
| Wood............. | 6.70 | 9.93 | 11.51 | 12.26 | 12.66 | 12.83 |
| Rubber and leather | 9.29 | 11.95 | 12.70 | 12.91 | 12.97 | 13.00 |

The values of $c$ for iron rope are one-half of those given. It is evident from these figures that when more than three laps are made it is immaterial what the surface is on which the rope tracks, as far as frictional adhesion is concerned.

From the foregoing formula, assuming the sheaves to be of equal diameter, and of a size not less than the minimum diameter given in the table, it is possible to find the horsepower that may be transmitted by a steel rope, as is shown in the accompanying table.

### HORSEPOWER THAT MAY BE TRANSMITTED BY A STEEL ROPE MAKING A SINGLE LAP ON WOOD-FILLED SHEAVES

| Diameter of Rope Inch | Velocity of Rope, in Feet per Second | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | 10 | 20 | 30 | 40 | 50 | 60 | 70 | 80 | 90 | 100 |
| | Horsepower That May Be Transmitted | | | | | | | | | |
| $\frac{1}{2}$ | 4 | 8 | 13 | 17 | 21 | 25 | 28 | 32 | 37 | 40 |
| $\frac{9}{16}$ | 7 | 13 | 20 | 26 | 33 | 40 | 44 | 51 | 57 | 62 |
| $\frac{5}{8}$ | 10 | 19 | 28 | 38 | 47 | 56 | 64 | 73 | 80 | 89 |
| $\frac{11}{16}$ | 13 | 26 | 38 | 51 | 63 | 75 | 88 | 99 | 109 | 121 |
| $\frac{3}{4}$ | 17 | 34 | 51 | 67 | 83 | 99 | 115 | 130 | 144 | 159 |
| $\frac{13}{16}$ | 22 | 43 | 65 | 86 | 106 | 128 | 147 | 167 | 184 | 203 |
| $\frac{7}{8}$ | 27 | 53 | 79 | 104 | 130 | 155 | 179 | 203 | 225 | 247 |
| $\frac{15}{16}$ | 32 | 63 | 95 | 126 | 157 | 186 | 217 | 245 | | |
| $\frac{1}{1}$ | 38 | 76 | 103 | 150 | 186 | 223 | | | | |
| $\frac{7}{8}$ | 52 | 104 | 156 | 206 | | | | | | |
| 1 | 68 | 135 | 202 | | | | | | | |

The horsepower that may be transmitted by iron ropes is one-half of the above.

The table gives the maximum amount of power capable of being transmitted under the conditions stated, so that when using wood-lined sheaves, it is well to make some allowance for the stretching of the rope, and to advocate somewhat heavier equipments than the table would give; that is, if it is desired to transmit 20 H. P., for instance, to put in a plant that would transmit 25 to 30 H.P., thus avoiding the necessity of having to take up a comparatively small amount of stretch. On rubber and leather filling, however, the amount of power capable of being transmitted is considerably greater than on wood, so that this filling is generally used; and in this case no allowance need be made for stretch, as such sheaves will likely transmit the power given by the table, under all possible deflections of the rope.

The transmission of more than 250 H. P. is impracticable with filled sheaves, because the tension is so great that the filling will quickly cut out, and the frictional adhesion on a metallic surface is insufficient where the rope makes but a single lap, or a half lap at either end of the line.

---

## TRANSMISSION BY HEMP ROPE

There is a growing tendency toward the substitution of hemp and cotton ropes for belting and line shafting as a means of transmitting power in large factories and shops. The advantages claimed for the rope-driving system are: (1) Economy; for a rope system is cheaper to install than either leather belting or shafting. (2) In the rope system, there is less loss of power by slipping. (3) Flexibility; that is, the ease with which the power is transmitted to any distance and in any direction.

In the United States, a single rope is carried round the pulley as many times as is necessary to produce the required power, and the necessary tension is obtained by passing the rope round a tension pulley weighted to give the desired tension. The ropes used in rope transmission are either of hemp, manila, or cotton; manila ropes are mostly used in the United States. They are of three strands, hawser laid, and may be from $\frac{1}{2}$ in. to 2 in. in diameter.

The weight of ordinary manila or cotton rope is about .3 $D^2$ lb. per ft. of length, where $D$ = diameter of rope, in inches. Letting $w$ = weight per foot of length, $w$ = .3 $D^2$. The breaking strength of the rope varies from 7,000 to 12,000 lb. per sq. in. of cross-section. The average value may be taken as 7,000 $D^2$, when $D$ is the diameter of rope.

For a continuous transmission, it has been determined by experiment that the best results are obtained when the tension in the driving side of the rope is about $\frac{1}{35}$ of the breaking strength. That is,

$$T_1 = \text{tension in tight side} = \frac{7,000\ D^2}{35} = 200\ D^2$$

The ropes run in **V**-shaped grooves, and the coefficient of friction is, of course, greater than on a smooth surface. The coefficient for grooves with sides at an angle of 45° may be taken at from .25 to .33.

The horsepower that can be transmitted by a single rope running under favorable conditions is given by the formula

$$H = \frac{v\ D^2}{825}\left(200 - \frac{v^2}{107.2}\right),$$

in which

$H$ = horsepower transmitted;
$D$ = diameter of rope, in inches;
$v$ = velocity of rope, in feet per second.

The maximum power is obtained at a speed of about 84 ft. per sec. For higher velocities, the centrifugal force becomes so great that the power is decreased, and when the speed reaches 145 ft. per sec. the centrifugal force just balances the tension, so that no power at all is transmitted. Consequently, a rope should not run faster than about 5,000 ft. per min., and it is preferable on the score of durability to limit the velocity to 3,500 ft. per min.

EXAMPLE.—A rope flywheel is 26 ft. in diameter, and makes 55 rev. per min. The wheel is grooved for 35 turns of $1\frac{1}{2}$ in. rope. What horsepower may be transmitted?

SOLUTION.—Velocity, in feet per second is

$$v = \frac{26 \times \pi \times 55}{60} = \frac{4,492}{60} = 74.9 \text{ ft.}$$

Applying the formula $H = \dfrac{v \, D^2}{825}\left(200 - \dfrac{v^2}{107.2}\right)$, the horsepower transmitted by one rope or turn is

$$\frac{74.9 \times (1\frac{1}{2})^2}{825} \times \left[200 - \frac{(74.9)^2}{107.2}\right] = 30.16.$$

Then, $30.16 \times 35 = 1,055.6$ H. P. transmitted by the 35 ropes.

EXAMPLE.—How many times should a 1-in. rope be wrapped around a grooved wheel in order to transmit 200 H. P., the speed being 3,500 ft. per min.?

SOLUTION.—3,500 ft. per min. = $3,500 \div 60 = 58\frac{1}{3}$ ft. per sec. Applying the formula, the horsepower transmitted with one turn is,

$$H = \frac{58\frac{1}{3} \times 1^2}{825} \times \left[200 - \frac{(58\frac{1}{3})^2}{107.2}\right] = 11.9$$

Hence, $200 \div 11.9 = 16.8$, say 17 turns.

Rope pulleys differ from belt pulleys only in their rims. The inclination of the sides of the grooves may vary from 30° to 60°. The more acute the angle, the greater the coefficient and, consequently, the wear on the rope.

The long radius $R$ is determined by drawing a line through the center of the rope at an angle of $22\frac{1}{2}°$ with the horizontal, and producing it until it intersects a line drawn through the tops of the ribs dividing the grooves, then, with this point of intersection as a center, drawing the curve forming the side of the groove tangent to the circumference of the rope. The advantage claimed for this groove is that the rope will turn more freely in it, thus presenting new sets of fibers to the sides of the grooves and increasing the life of the rope.

The diameter of a rope pulley should be at least 30 times the diameter of the rope. Good results are obtained when the diameters of pulleys and idlers on the driving side are 40 times, and those on the driven side 30 times, the rope diameter. Idlers used simply to support a long span may have diameters as small as 18 rope diameters, without injuring the rope.

When possible, the lower side of the rope should be the driving side, for in that case the rope embraces a greater portion of the circumference of the pulley, and increases the arc of contact.

When the continuous system of rope transmission is used, the tension pulley should act on as large an amount of rope as possible. It is good practice to use a tension pulley and carriage for every 1,200 ft. of rope, and have at least 10% of the rope subjected directly to the tension.

Aside from the grooved rim, rope pulleys are constructed the same as other pulleys. They may be cast solid, in halves, or in sections. The pulley grooves must be turned to exactly the same diameter; otherwise, the rope will be severely strained.

## HORSEPOWER OF MANILA ROPES

*(Link-Belt Engineering Co.)*

| Diam. of Rope Inches | Weight per Foot Pounds | Breaking Strain Pounds | Working Strain Pounds | 1,000 Ft. per Min. | | 2,000 Ft. per Min. | | 3,000 Ft. per Min. | | 4,000 Ft. per Min. | | 5,000 Ft. per Min. | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | | H.P. | Tens. Wt. | H.P. | Tens. Wt. | H.P. | Tens. Wt. | H.P. | Tens. Wt. | H.P. | Tens. Wt. |

## LINE SHAFTING

*Shafting* is usually made cylindrically true, either by a special rolling process, when it is known as *cold-rolled shafting*, or it is turned up in a machine called a *lathe*. In the latter case, it is called *bright shafting*. What is known as *black shafting* is simply bar iron rolled by the ordinary process and turned where it receives the couplings, pulleys, bearings, etc.

Bright turned shafting varies in diameter by $\frac{1}{4}$ in. up to about $3\frac{1}{2}$ in.; above this the diameter of the shafting varies by $\frac{1}{2}$ in. The actual diameter of a bright shaft is $\frac{1}{16}$ in. less than the commercial diameter, it being designated from the diameter of the ordinary round bar iron from which it is turned. Thus, a length of what is called 3-in. bright shafting is only $2\frac{15}{16}$ in. in diameter. Cold-rolled shafting is designated by its commercial diameter; thus, a length of what is called 3-in. shafting is 3 in. in diameter.

### CONSTANTS FOR LINE SHAFTING

| Material of Shaft | No Pulleys Between Bearings | With Pulleys Between Bearings |
|---|---|---|
| Steel or cold-rolled iron. | 65 | 85 |
| Wrought iron............ | 70 | 95 |
| Cast iron.............. | 90 | 120 |

Cold-rolled iron is considerably stronger than ordinary turned wrought iron, the increased strength being due to the process of rolling, which seems to compress the metal and so make it denser—not merely skin deep, but practically throughout the whole diameter.

Let

$D$ = diameter of shaft;
$R$ = revolutions per minute;
$H$ = horsepower transmitted;
$C$ = constant given in table.

In the above table the bearings are supposed to be spaced so as to relieve the shaft of excessive bending; also, in the third vertical column, an average number and weight of pulleys and power given off is assumed.

When determining these constants allowance was made to insure the stiffness as well as strength of the shaft.

$$H = \frac{D^3R}{C} \qquad D = \sqrt[3]{\frac{CH}{R}} \qquad R = \frac{CH}{D^3}$$

Shafts are subject to forces that produce stresses of two kinds—transverse and torsional. When the machines to be driven are below the shaft, there is a transverse stress on the shaft, due to the weight of the shaft itself, of the pulley and the tension of the belt. Sometimes, the power is taken off horizontally on one side, in which case the tension of the belt produces a horizontal transverse stress, while the weight of the pulley acts with the weight

### MAXIMUM DISTANCE BETWEEN BEARINGS

| Diameter of Shaft Inches | Distance Between Bearings Feet | |
|---|---|---|
| | Wrought-Iron Shaft | Steel Shaft |
| 2 | 11 | 11.50 |
| 3 | 13 | 13.75 |
| 4 | 15 | 15.75 |
| 5 | 17 | 18.25 |
| 6 | 19 | 20.00 |
| 7 | 21 | 22.25 |
| 8 | 23 | 24.00 |
| 9 | 25 | 26.00 |

of the shaft to produce a vertical transverse stress. When the machinery to be driven is placed on the floor above the shaft, the tension of the belt produces a transverse stress in an opposite direction to that due to the weight of the shaft and pulley.

The torsional strength of shafts, or their resistance to breaking by twisting, is proportional to the cube of their diameter. Their stiffness or resistance to bending is proportional to the fourth power of their diameters, and inversely

proportional to the cube of the lengths of their spans. No simple general formula can be given that will safely apply to engine and other shafting that is subjected to the bending stresses produced by overhung cranks, the weight of heavy flywheels, the pull of large belts, or to severe shocks produced by the intermittent action of the power or load. The calculations for such shafts should always be based on the special conditions involved.

In the preceding table are given the maximum distances between the bearings of some continuous shafts that are used for the transmission of power. Pulleys from which considerable power is to be taken should always be placed as close to a bearing as possible.

The diameters of the different lengths of shafts composing a line of shafting may be proportional to the quantity of power delivered by each respective length. In this connection, the positions of the various pulleys depend on the distance between the pulley and the bearing, and on the amount of power given off by the pulleys. Suppose, for example, that a piece of shafting delivers a certain amount of power; then, the shaft will deflect or bend less if the pulley transmitting that power is placed close to a hanger or bearing, than if it is placed midway between the two hangers or bearings. It is impossible to give any rule for the proper distance of bearings that could be used universally, as in some cases the requirements demand that the bearings be nearer together than in others. If the work done by a line of shafting is distributed quite equally along its entire length, and the power can be applied near the middle, the strength of the shaft need be only one-half as great as when the power is applied at one end of the shaft.

### HORSEPOWER SHAFTING WILL TRANSMIT

| Diameter of Shaft Inches | Revolutions per Minute | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | 100 | 125 | 150 | 175 | 200 | 225 | 250 | 300 | 350 | 400 |
| | Horsepower Transmitted | | | | | | | | | |
| 1 1/16 | 1.2 | 1.4 | 1.7 | 2.1 | 2.4 | 2.6 | 3.1 | 3.6 | 4.3 | 5.0 |
| 1 3/16 | 2.4 | 3.1 | 3.7 | 4.3 | 4.9 | 5.5 | 6.1 | 7.3 | 8.5 | 9.7 |
| 1 7/16 | 4.3 | 5.3 | 6.4 | 7.4 | 8.5 | 9.5 | 10.5 | 12.7 | 14.8 | 16.9 |
| 1 11/16 | 6.7 | 8.4 | 10.1 | 11.7 | 13.4 | 15.1 | 16.7 | 20.1 | 23.4 | 26.8 |
| 1 15/16 | 10.0 | 12.5 | 15.0 | 17.5 | 20.0 | 22.5 | 25.0 | 30.0 | 35.0 | 40.0 |
| 2 3/16 | 14.3 | 17.8 | 21.4 | 24.9 | 28.5 | 32.1 | 35.6 | 42.7 | 49.8 | 57.0 |
| 2 7/16 | 19.5 | 24.4 | 29.3 | 34.1 | 39.0 | 44.1 | 48.7 | 58.5 | 68.2 | 78.0 |
| 2 11/16 | 26.0 | 32.5 | 39.0 | 43.5 | 52.0 | 58.5 | 65.0 | 78.0 | 87.0 | 104.0 |
| 2 15/16 | 33.8 | 42.2 | 50.6 | 59.1 | 67.5 | 75.9 | 84.4 | 101.3 | 118.2 | 135.0 |
| 3 3/16 | 43.0 | 53.6 | 64.4 | 75.1 | 85.8 | 95.6 | 107.3 | 128.7 | 150.3 | 171.6 |
| 3 7/16 | 53.6 | 67.0 | 79.4 | 93.8 | 107.2 | 120.1 | 134.0 | 158.8 | 187.6 | 214.4 |
| 3 11/16 | 65.9 | 82.4 | 97.9 | 115.4 | 121.8 | 148.3 | 164.8 | 195.7 | 230.7 | 243.6 |
| 3 15/16 | 80.0 | 100.0 | 120.0 | 140.0 | 160.0 | 180.0 | 200.0 | 240.0 | 280.0 | 320.0 |
| 4 7/16 | 113.9 | 142.4 | 170.8 | 199.3 | 227.8 | 256.2 | 284.7 | 341.7 | 398.6 | 455.6 |
| 4 15/16 | 156.3 | 195.3 | 234.4 | 273.4 | 312.5 | 351.5 | 390.6 | 468.7 | 546.8 | 625.0 |

### BELT PULLEYS

**Solid and Split Pulleys.**—Besides being used with ropes or chains for the hoisting of loads, pulleys are extensively employed with belts for transmitting power. Belt pulleys may be divided into two classes, namely, solid pulleys and split pulleys. A *solid pulley* is one in which the arms, hub, and rim are cast in one solid piece. A *split pulley* is one that is cast in halves that are afterwards bolted together; the latter style of pulley is more readily placed on or removed from a shaft than is the solid pulley. Pulleys are generally cast in halves or parts when they are more than 6 ft. in diameter. This is done on account of the shrinkage strains in large pulley castings, which render the pulleys liable to crack as a result of unequal cooling of the metal.

**Wooden Pulleys.**—Although most belt pulleys are made of cast iron, wrought iron, and steel, wooden pulleys have come into extensive use. These are built of segments of wood, usually maple, securely glued together. It is possible to procure wooden split pulleys that are fitted with removable bushings, thus allowing the same pulley to be adapted readily to shafting of different diameters. Wooden pulleys are somewhat lighter than cast-iron pulleys for the same service.

**Driving and Driven Pulleys.**—The pulley that imparts motion to the belt is called the *driving pulley*, or the *driver*, and the one that receives motion from the belt is called the *driven pulley*, or simply the *driven*. When two pulleys are connected by a belt, the speeds at which the pulleys run are inversely proportional to their diameters. Thus, if two pulleys have diameters of 12 in. and 24 in., the speed of the smaller is to the speed of the larger as 24 to 12, or as 2 to 1. The speed of a pulley or of a shaft is usually stated in revolutions per minute, abbreviated rev. per min. or R. P. M.

**Diameter and Speed of Driver.**—It often becomes necessary to calculate the size or the speed of a pulley that drives or is being driven by a machine.

Let $D$ = diameter of driving pulley, in inches;
$d$ = diameter of driven pulley, in inches;
$N$ = number of rev. per min. of driving pulley;
$n$ = number of rev. per min. of driven pulley.

Then, if the diameter of the driven and the required speeds of both pulleys are given, the diameter of the driver may be found by the formula

$$D = \frac{dn}{N} \quad (1)$$

If the speed of the driver is to be found, it is necessary to use the formula

$$N = \frac{dn}{D} \quad (2)$$

**Example.**—A 12-in. pulley on a certain machine is to run at 160 rev. per min. and is to be driven by belt from a pulley on the shaft of an engine that make 96 rev. per min. What must be the diameter of the pulley on the engine shaft?

**Solution.**—Substituting in formula 1,

$$D = \frac{12 \times 160}{96} = 20 \text{ in.}$$

**Diameter and Speed of Driven.**—If the diameter of the driving pulley and the desired speeds of both pulleys are known, the required diameter of the driven pulley may be found by the formula

$$d = \frac{DN}{n} \quad (1)$$

If the speed of the driven pulley is to be found, it is necessary to use the formula

$$n = \frac{DN}{d} \quad (2)$$

**Example 1.**—A 30-in. pulley on a line shaft running at 120 rev. per min. is to drive a pulley on a machine at 300 rev. per min. What must be the diameter of the pulley on the machine?

**Solution.**—Substituting in formula 1,

$$d = \frac{30 \times 120}{300} = 12 \text{ in.}$$

**Example 2.**—A driving pulley 48 in. in diameter makes 175 rev. per min. and is connected by belt to a driven pulley 14 in. in diameter. What is the speed of the driven pulley?

**Solution.**—Substituting in formula 2,

$$n = \frac{48 \times 175}{14} = 600 \text{ rev. per min.}$$

---

# BELTING

A *belt* is a flexible band by which motion is transmitted from one pulley to another. The materials most commonly used for belts are leather, cotton, and rubber, although thin, flat bands of steel are coming into use. Leather belts are usually made either single or double. A *single belt* is one composed of a single thickness of leather, and a *double belt* is one composed of two thicknesses

of leather cemented and riveted together throughout the whole length of the belt. Still heavier belts, consisting of three or four thicknesses of leather, and known as *triple* or *quadruple belts*, are sometimes made for heavy drives. Cotton belts are made up of a number of layers, or plies, sewed together and treated with a water-proofing substance. They are termed *two-ply, three-ply*, etc., according to the number of plies they contain. Four-ply cotton belting is usually considered equal to single leather belting. Rubber belts are particularly adapted for use in damp or wet places. They withstand changes of temperature without injury, are durable, and are said to be less liable to slip than are leather belts.

**Sag of Belts.**—The distance between pulley centers depends on the size of the pulleys and of the belt; it should be great enough so that the belt will run with a slight sag and a gently undulating motion, but not great enough to cause excessive sag and an unsteady flapping motion of the belt. In general, the centers of small pulleys carrying light narrow belts should be about 15 ft. apart and the belt sag $1\frac{1}{2}$ to 2 in.; for large pulleys and heavy belts the distance should be 20 to 30 ft. and the sag $2\frac{1}{2}$ to 5 in. Loose-running belts will last much longer than tight ones, and will be less likely to cause heating and wear of bearings.

**Speed of Belts.**—The higher the speed of a belt, the less may be its width to transmit a given horsepower; consequently, a belt should be run at as high a speed as conditions will permit. The greatest allowable speed for a belt joined by lacing is about 3,500 ft., per min. for ordinary single and double leather belts. For belts joined by cementing, when the joint has about the same strength as the solid belt, the velocity may be as high as 5,000 ft. per min. Higher speeds than these have been used, but there is little to be gained by exceeding about 4,800 ft. per min. In choosing a proper belt speed, due regard must be paid to commercial conditions. Although a high speed of the belt means a narrow and cheaper belt, the increased cost of the larger pulleys that may be required may offset the gain due to the high speed of the belt, at least so far as the first cost is concerned. The speed of a belt, in feet per minute, may be found by multiplying the number of revolutions per minute of the pulley by 3.1416 times the diameter of the pulley, in inches, and dividing the product by 12.

**Horsepower of Belts.**—The pull on a belt is greatest on the tight, or driving, side, and least on the slack side. The difference between the tensions, or pulls, in these two sides is called the *effective pull*. The effective pull that may be allowed per inch of width for single leather belts with different arcs of contact is given in the accompanying table. The *arc of contact* is the portion of the circumference of the smaller pulley that is covered by the belt. The horsepower that can be transmitted by a single leather belt may be found by the formula

$$H = \frac{CWV}{33,000}. \quad (1)$$

in which
$H$ = horsepower of belt;
$C$ = effective pull, taken from table;
$W$ = width of belt, in inches;
$V$ = speed of belt, in feet per minute.

If it is desired to find the width of single belt required to transmit a given horsepower, the formula becomes

$$W = \frac{33,000H}{CV} \quad (2)$$

**EXAMPLE 1.**—What horsepower can be transmitted by a single leather belt 4 in. wide running at a speed of 2,500 ft. per min., if the belt covers one-third of the circumference of the small pulley?

**SOLUTION.**—The fraction of the circumference covered by the belt is $\frac{1}{3} = .333$. From the table, the allowable effective pull corresponding to this value is 28.8. Substituting in formula 1,

$$H = \frac{28.8 \times 4 \times 2,500}{33,000} = 8.7 \text{ H. P.}$$

**EXAMPLE 2.**—A single leather belt is to run at a speed of 3,000 ft., per min. and is to transmit 18 H. P. Find the width of the belt, if the arc of contact is 150°.

**SOLUTION.**—The effective pull corresponding to an arc of contact of 150°, from the table, is 33.8. Substituting in formula 2,

$$W = \frac{33,000 \times 18}{33.8 \times 3,000} = 5.9 \text{ in.}$$

A 6-in. belt would be used.

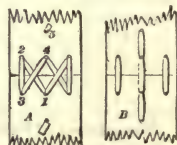
## ALLOWABLE EFFECTIVE PULL

| Arc of Contact | | Allowable Effective Pull |
| --- | --- | --- |
| Degrees | Fraction of Circumference | Pounds per Inch of Width |
| 90 | .250 | 23.0 |
| 112½ | .312 | 27.4 |
| 120 | .333 | 28.8 |
| 135 | .375 | 31.3 |
| 150 | .417 | 33.8 |
| 157½ | .437 | 34.9 |
| 180 or over | .500 or over | 38.1 |

The horsepower of a double leather belt may be taken as 1⅔ times that of a single leather belt of the same width running under the same conditions. Accordingly, the width of a double leather belt required for any service is only $\frac{7}{10}$ that of a single belt for the same service.

**Lacing of Belts.**—A very satisfactory way of lacing belts less than 3 in. wide is shown in Fig. 1, in which *A* is the outside of the belt and *B* is the side that runs against the face of the pulley. The ends of the belt are first cut square, and then holes are punched in the ends, in corresponding positions opposite one another. The number of holes in each row should always be odd, in the style of lacing shown, using three holes in belts up to 2 in. wide and five holes in belts between 2 and 3 in. wide. The lacing is first drawn through one of the middle holes from the under side, or pulley side, at *1*. Then it is drawn across the upper side and is passed down through *2*, across under the belt to *3*, up through *3*, across and down again through *2*, back under the belt and up through *3* again,

FIG. 1

then across and down through *4* and finally up through *5*, where a barb is cut in the edge of the lacing to prevent it from pulling out. This completes the lacing of one half. The other end of the lacing is then carried through the holes in the other half, in the same order.


For belts wider than 3 in., the lacing shown in Fig. 2 may be used. In this case, there are two rows of holes in each end of the belt to be joined. The row nearer the end of the belt should have one more hole than the row farther away. For belts up to 4½ in. wide use three holes in the first row and two holes in the second row. For belts up to 6 in. wide, use four and three holes, respectively. For wider belts, make the total number of holes in both rows

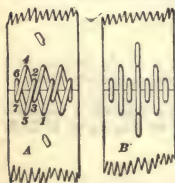


FIG. 2

either one or two more than the number of inches of width of the belt, the object being to get an odd total number of holes. For example, a 10-in. belt should have eleven holes, and a 13-in. belt should have fifteen holes. The outside holes of the first row should not be nearer the side edges of the belt than ¾ in. and not nearer the joint edge than ⅞ in. The second row should be at least 1½ in. from the joint edge. In Fig. 2, *A* is the outside face and *B* the face next the pulley. The lacing is first drawn up through *1* from the pulley side, and then is carried through *2*, *3*, *4*, *5*, *6*, *7*, *6*, *7*, *4*, *5*, *2*, *3*, *8*, and out at *9* to be fastened. The other end of the lacing is used on the other half of the belt in the same way.

**Care and Use of Belts.**—It is a much disputed question as to which side of a leather belt should be run next to the pulley. The more common practice, it is believed, is to run the belt with the hair, or grain, side nearest the pulley. This side is harder and more liable to crack than the flesh side; by running it on the inside, the tendency is to cramp or compress it as it passes over the pulley, while, if it ran on the outside, the tendency would be for it to stretch

and crack. The flesh side is the tougher side, but for the reason just given the life of the belt will be longer if the wear comes on the grain side. The lower side of the belt should be the driving side, the slack side running from the top of the driving pulley. The sag of the belt will then cause it to encompass a greater length of the circumference. Long belts, running in any other direction than vertical, work better than short ones, as their weight holds them more firmly to their work.

It is bad practice to use rosin to prevent slipping. Rosin gums the belt, causes it to crack, and prevents slipping for only a short time. If a belt in good condition persists in slipping, a wider belt should be used. Sometimes, larger pulleys on the driving and driven shafts are of advantage, as they increase the belt speed and reduce the stress on the belt. Belts may be kept soft and pliable by being oiled once a month with castor oil or neat's-foot oil.

When rubber belts are used, animal oils or animal grease should never be used on them. If the belt should slip, it may be lightly moistened on the side nearest the pulley with boiled linseed oil.

**Flapping of Belts.**—One of the most annoying troubles experienced with belting of all kinds is the violent flapping of the slack side. Flapping may be due to one or both of the pulleys running out of true, causing the belt to be alternately stretched and released. This will usually cause a belt to flap when running at a high speed. If the belt is rather slack, tightening it may lessen or stop the flapping. Another frequent cause of the flapping of a belt is the want of alinement of the pulleys. To remedy this, the pulleys should be brought in line; should this fail, the belt should be tightened if it is rather loose. If no improvement is noticed and it is not possible to turn the pulleys, the belt speed should be reduced a little, either by the substitution of smaller pulleys or by changing the speed of the driving shaft, according to circumstances.

With belts running at speeds above 4,000 ft. per min., flapping may occur when the pulleys are perfectly true and in line with each other, even when the belt has the proper tension. This is believed to be due to air becoming entrapped between the face of the pulley and the belt; in this case the trouble may be prevented by perforating the belt with a series of small holes. Perforated belts may now be bought in the market.

Another cause of flapping is that the distance between the pulleys may be too great. In general, the distance between the pulleys should not exceed 15 ft. for belts up to 4 in. wide; 20 ft. for belts from 4 to 12 in.; 25 ft., from 12 to 18 in.; and 30 ft., for wider belts. A belt that is not joined square will flap, especially when running at a rather high speed.

---

# SPECIFIC GRAVITY, WEIGHT, AND OTHER PROPERTIES OF MATERIALS

## DEFINITIONS

The specific gravity of a body is the ratio of its weight to the weight of an equal bulk of pure water, at a standard temperature (62° F. = 16.670° C.). Some experimenters have used 60° F. as the standard temperature, others 32° and still others, 39.1°. To reduce a specific gravity, referred to water at 39.1° F., to the standard of water at 62° F., multiply by 1.00112.

**Rule I.**—*Given the specific gravity referred to water at 62° F., multiply by 62.355 to find the weight of 1 cu. ft. of the substance.*

**Rule II.**—*Given weight per cubic foot, to find specific gravity, multiply by .016037.*

**Rule III.**—*Given specific gravity, to find the weight per cubic inch, multiply by .036085.*

**To Find the Specific Gravity of a Solid Heavier Than Water.**—Weigh the body both in air and in water, and divide the weight in air by the difference of the weights in air and water.

EXAMPLE.—If a piece of coal weighs 480 gr. in air and weighs 82 gr. in water, what is its specific gravity?

SOLUTION.—As 480 − 82 = 398, or loss of weight in water. Then 480 ÷ 398 = 1.206, the specific gravity of coal.

**To Find the Specific Gravity of a Solid Lighter Than Water.**—Attach to it another body heavy enough to sink it; weigh severally the compound mass and the heavier body in water, divide the weight of the body in air by the weight of the body in air plus the weight of the sinker in water minus the combined weight of the sinker and body in water.

**To Find the Specific Gravity of a Fluid.**—Weigh both in and out of the fluid a solid (insoluble) of known specific gravity, and divide the product of the weight lost in the fluid and the specific gravity of the solid by the weight of the solid.

The weight of 1 cu. ft. of water at a temperature of 62° is about 1,000 oz. avoir., and the specific gravity of a body, multiplied by 1,000, shows the weight of 1 cu. ft. of that body in ounces avoirdupois. Then, if the magnitude of the body is known, its weight can be computed; or, if its weight is known, its magnitude can be calculated, provided its specific gravity is known; or, of the magnitude, weight, and specific gravity, any two being known, the third may be found.

**To Find the Weight of a Body, in Ounces, From Its Magnitude.**—Multiply the magnitude of the body in cu. ft., by the specific gravity of the substance multiplied by 1,000.

**To Find the Magnitude of a Body, in Cubic Feet, From Its Weight.**—Divide the weight of the body in ounces by 1,000 times the specific gravity of the body.

NOTE.—The specific gravity of any substance is equal to its weight in grams per cubic centimeter.

---

# SPECIFIC GRAVITY OF COMMON SUBSTANCES
## SPECIFIC GRAVITY OF MINERALS AND EARTHS

| Material | Specific Gravity | Material | Specific Gravity |
|---|---|---|---|
| Alabaster, gypseous ... | 2.31 | Lime, quick........... | 1.50 |
| Alabaster, calcareous .. | 2.76 | Limestone............ | 2.70 |
| Alum................ | 1.72 | Magnetic iron ore..... | 5.09 |
| Amethyst............ | 3.92 | Malachite............ | 4.01 |
| Asbestos, starry....... | 3.07 | Marble, African....... | 2.71 |
| Asphaltum........... | 1.40 | Marble, common...... | 2.67 |
| Barytes (heavy spar).. | 3.05 to 3.38 | Marble, Egyptian..... | 2.67 |
| Bluestone............ | 2.45 to 3.00 | Marble, Parian....... | 2.84 |
| Borax............... | 1.71 | Marble, Italian, white. | 2.71 |
| Bort (black diamond).. | 3.50 | Marl................ | 1.60 to 2.34 |
| Brick............... | 2.00 | Mica................ | 2.80 |
| Chalk............... | 2.78 | Niter................ | 1.90 |
| Clay................ | 1.90 | Opal................ | 2.09 |
| Coral, red........... | 2.70 | Phosphorus.......... | 1.77 |
| Diamond............ | 3.50 to 3.53 | Plaster of Paris....... | 1.87 to 2.47 |
| Earth, loose......... | 1.36 | Potash.............. | 2.10 |
| Emerald............. | 3.95 | Quartz.............. | 2.66 |
| Emerald, aquamarine.. | 2.73 | Rotten stone......... | 1.98 |
| Emery.............. | 4.00 | Ruby............... | 3.95 |
| Feldspar............ | 2.60 | Salt, common........ | 2.13 |
| Flint, black......... | 2.58 | Saltpeter............ | 2.09 |
| Flint, white......... | 2.59 | Sand................ | 2.65 |
| Garnet............. | 3.60 to 4.20 | Sandstone........... | 2.08 to 2.52 |
| Glass, bottle........ | 2.73 | Sapphire............ | 3.98 |
| Glass, flint......... | 3.50 | Serpentine.......... | 2.81 |
| Glass, green........ | 2.64 | Shale............... | 2.60 |
| Glass, white........ | 2.90 | Slate............... | 2.80 |
| Granite, Patapsco..... | 2.64 | Soil, common........ | 1.98 |
| Granite, Quincy...... | 2.65 | Specular iron ore..... | 5.25 |
| Granite, Scotch...... | 2.62 | Stone, mill.......... | 2.48 |
| Granite, Susquehanna. | 2.70 | Sulphur, native....... | 2.03 |
| Graphite............ | 2.20 | Talc................ | 2.90 |
| Grindstone.......... | 2.14 | Topaz............... | 3.50 |
| Gypsum, opaque...... | 2.17 | Tourmaline.......... | 2.07 |
| Jasper.............. | 2.65 | Turquoise........... | 2.84 |
| Lapis lazuli......... | 2.96 | Zircon.............. | 4.50 |

## SPECIFIC GRAVITY OF METALS

| Metal | Specific Gravity | Metal | Specific Gravity |
|---|---|---|---|
| Aluminum, wrought | 2.660 | Magnesium | 1.740 |
| Antimony | 6.712 | Manganese | 8.000 |
| Bismuth | 9.746 | Mercury, solid, at −40° F | 15.632 |
| Brass, common | 8.500 | Mercury, liquid, at 32° F | 13.619 |
| Brass, wire | 8.548 | Mercury, liquid, at 60° F | 13.580 |
| Bronze, bell-metal | 8.060 | Mercury, liquid, at 212° F | 13.375 |
| Bronze, gun-metal | 8.500 | Molybdenum | 8.620 |
| Calcium | 1.580 | Nickel, cast | 8.280 |
| Chromium | 6.000 | Platinum, hammered | 20.337 |
| Cobalt | 8.500 | Platinum, rolled | 21.042 |
| Copper, cast | 8.700 | Platinum, wire | 22.009 |
| Copper, pure | 8.788 | Potassium | .860 |
| Copper, wire and rolled | 8.878 | Silver, pure | 10.474 |
| Gold, hammered | 19.361 | Sodium | .970 |
| Gold, pure, cast | 19.258 | Steel, cast | 7.919 |
| Gold, 22 carat fine | 17.486 | Steel, common, soft | 7.833 |
| Iridium | 18.680 | Steel, hard and tempered | 7.818 |
| Iron, cast | 7.207 | Tin, Bohemian | 7.312 |
| Iron, hammered | 7.780 | Tin, English | 7.201 |
| Iron, pure | 7.768 | Titanium | 5.300 |
| Iron, wrought and rolled | 7.780 | Tungsten | 17.600 |
| Lead, hammered | 11.388 | Zinc, cast | 6.860 |
| Lead, pure | 11.330 | Zinc, rolled | 7.101 |

## SPECIFIC GRAVITY OF LIQUIDS

| Liquid | Specific Gravity | Liquid | Specific Gravity |
|---|---|---|---|
| Acid, acetic | 1.062 | Cider | 1.018 |
| Acid, hydrochloric | 1.200 | Egg | 1.090 |
| Acid, nitric | 1.217 | Ether, sulphuric | .739 |
| Acid, phosphoric | 1.558 | Honey | 1.450 |
| Acid, sulphuric | 1.841 | Human blood | 1.054 |
| Alcohol, commercial | .833 | Milk | 1.032 |
| Alcohol, proof-spirit | .925 | Oil, linseed | .940 |
| Alcohol, pure | .792 | Oil, olive | .915 |
| Alcohol, wood | .800 | Oil, turpentine | .870 |
| Beer, lager | 1.034 | Oil, whale | .932 |
| Bordeaux, wine | .992 | Petroleum | .878 |
| Bromine | 2.996 | Water, distilled | 1.000 |
| Champagne | .997 | Water, sea | 1.030 |
| Chloroform | 1.530 | Wine | .992 |

## SPECIFIC GRAVITY OF GASES AND VAPORS

| Gas or Vapor | Specific Gravity | Gas or Vapor | Specific Gravity |
|---|---|---|---|
| Air, 32° F. and 1 atmos. | 1.000 | Methane | .553 |
| Alcohol, vapor | 1.589 | Nitrogen | .917 |
| Ammonia | .589 | Olefiant gas | .967 |
| Bromine vapor | 4.540 | Oxygen | 1.106 |
| Carbon dioxide | 1.520 | Smoke, bituminous coal | .102 |
| Carbon monoxide | .967 | Smoke, wood | .900 |
| Chlorine | 2.450 | Steam at 212° F | .488 |
| Chloroform, vapor | 5.300 | Sulphureted hydrogen | 1.1912 |
| Hydrogen | .069 | Turpentine vapor | 4.700 |
| Mercury vapor (ideal) | 6.974 | Water vapor | .623 |

## SPECIFIC GRAVITY OF DRY WOODS

| Wood | Specific Gravity | Wood | Specific Gravity |
|---|---|---|---|
| Alder | .80 | Hazel | .60 |
| Apple | .89 | Lemon | .70 |
| Ash | .86 | Lignum vitae | 1.33 |
| Bay | .82 | Linden | .60 |
| Beech | .85 | Logwood | .91 |
| Box, French | .96 | Mahogany, Honduras | .56 |
| Box, Dutch | 1.33 | Maple | .79 |
| Box, Brazilian, red | 1.03 | Mulberry | .90 |
| Cedar, wild | .60 | Oak | .95 |
| Cedar, Palestine | .61 | Orange | .71 |
| Cedar, American | .56 | Pear | .66 |
| Cherry | .67 | Pine, southern | .72 |
| Cork | .25 | Pine, white | .40 |
| Ebony, American | 1.22 | Poplar | .38 |
| Elder | .70 | Poplar, white Spanish | .53 |
| Elm | .56 | Sassafras | .48 |
| Filbert | .60 | Spruce | .50 |
| Fir, male | .55 | Spruce, old | .46 |
| Fir, female | .50 | Walnut | .61 |

## SPECIFIC GRAVITY OF MISCELLANEOUS SUBSTANCES

| Substance | Specific Gravity | Substance | Specific Gravity |
|---|---|---|---|
| Amber | 1.085 | India rubber | .935 |
| Air | .0012 | Ivory | 1.822 |
| Beeswax | .965 | Lard | .947 |
| Bone | 1.8 to 2.0 | Pearl, oriental | 2.650 |
| Butter | .942 | Spermaceti | .943 |
| Cotton | 1.950 | Sugar | 1.605 |
| Fat | .923 | Tallow, sheep and ox | .923 |
| Gunpowder, loose | .900 | Tallow, calf | .934 |
| Gunpowder, shaken | 1.000 | Tar | 1.000 |
| Gum Arabic | 1.452 | Wool | 1.610 |

# AVERAGE WEIGHT OF VARIOUS SUBSTANCES
## WEIGHT OF 1 CU. FT. OF VARIOUS METALS

| Metal | Weight Pounds | Metal | Weight Pounds |
|---|---|---|---|
| Aluminum | 167 | Magnesium | 109 |
| Antimony | 418 | Manganese | 499 |
| Bismuth | 613 | Mercury, at 32° F. | 849 |
| Brass, cast | 504 | Mercury, at 60° F. | 846 |
| Brass, rolled | 524 | Mercury, at 212° F. | 836 |
| Bronze | 546 | Molybdenum | 538 |
| Chromium | 456 | Nickel | 548 |
| Cobalt | 560 | Platinum, hammered | 1,270 |
| Copper, cast | 552 | Platinum, rolled | 1,313 |
| Copper, rolled | 555 | Platinum, wire | 1,372 |
| Gold, cast, 24 carat | 1,204 | Silver, hammered | 657 |
| Gold, pure, hammered | 1,217 | Silver, pure | 653 |
| Gun-metal bronze | 529 | Sulphur | 125 |
| Iridium | 1,400 | Steel | 490 |
| Iron, cast | 450 | Tin | 458 |
| Iron, wrought | 480 | Tungsten | 1,097 |
| Lead, commercial, cast | 712 | Zinc | 437 |

## WEIGHT OF 1 CU. FT. OF VARIOUS WOODS, WHEN DRY*

| Wood | Weight Pounds | Wood | Weight Pounds |
|---|---|---|---|
| | | Cypress, bald | 29 |
| Alder | 42 | Cypress, Spanish | 40 |

| Catalpa, hardy | 25 | Ironwood, or blue beech | 45 |
| Cedar, California, white | 25 | Ironwood, or hop hornbeam | 51 |
| Cedar, canoe | 23 | Jasmine, Spanish | 48 |
| Cedar, incense | 25 | Joshua tree | 23 |
| Cedar, Indian | 82 | Juneberry | 54 |
| Cedar, juniper | 35 | Karri | 63 |
| Cedar, Palestine | 38 | Kauri | 37 |
| Cedar, Port Oxford | 28 | Laburnum | 57 |
| Cedar, red | 30 | Lancewood | 53 |
| Cedar, white, or post | 23 | Larch | 38 |
| Cedar, white (arbor vitæ) | 19 | Larch, tamarack | 46 |
| Cedar, wild | 37 | Laurel, California | 40 |
| Cedar, yellow | 29 | Laurel, Madroña | 43 |
| Cherry, wild black | 36 | Lemon | 45 |
| Chestnut | 28 | Lignum vitæ | 83 |
| Chinkapin | 36 | Linden | 38 |
| Citron | 45 | Locust, black, or yellow | 45 |
| Cocoa wood | 65 | Locust, honey | 42 |
| Cocobolo | 55 | Logwood | 58 |
| Cottonwood | 24 | Madroña | 43 |
| Cottonwood, black | 23 | Mahoe | 41 |
| Cucumber tree | 29 | Mahogany | 45 |

*The weight of wood depends largely on the amount of moisture it contains. The weights in this and the following tables are for very dry wood and not for green wood. Separate tables are given for Philippine, Indian, and Australian woods. The weight of moisture contained in the wood must be added to the values given in these tables.

## WEIGHT OF 1 CU. FT. OF AUSTRALIAN WOODS, WHEN DRY*

| Wood | Weight Pounds |
|------|------|
| Acacia dealbata (silver wattle) | 57 |
| Acacia decurrens (common wattle) | 47 |
| Acacia implexa | 44 |
| Acacia melanoxylon (blackwood; lightwood) | 47 |
| Acacia mollissima (silver wattle) | 50 |
| Acacia pycnantha (golden wattle) | 52 |
| Acacia salicina | 48 |
| Araucaria cunninghamii (pine) | 45 |
| Aster argophyllus (musk tree) | 40 |
| Banksia integrifolia (coast honeysuckle tree) | 50 |
| Banksia marginata (common honeysuckle tree) | 38 |
| Banksia serrata (heath honeysuckle tree) | 50 |
| Callitris verrucosa (dessert sandarac pine, or cypress) | 43 |
| Castanaspermum australe (black bean) | 57 |
| Casuarina torulusa (forest oak) | 66 |
| Casuarina quadravalvis (drooping she oak) | 61 |
| Cedrela australis (cedar) | 28 |
| Ceratopetalum apetalum (coachwood) | 42 |
| Dacrydium cupressinum (rimu) | 38 |
| Dissiliaria baloghioides (teak) | 60 |
| Dysoxylon muelleri (red bean) | 46 |
| Eucalyptus amygdalina regnans (mountain ash or peppermint tree) | 60 |
| Eucalyptus botryoides (blue gum, Gippsland mahogany, or bastard mahogany) | 60 |
| Eucalyptus corymbosa (bloodwood) | 58 |
| Eucalyptus corynocalyx (sugar gum) | 69 |
| Eucalyptus diversicolor (karri) | 61 |
| Eucalyptus globulus (blue gum) | 57 |
| Eucalyptus gomphocephala (tuart) | 66 |
| Eucalyptus goniocalyx (bastard box, spotted gum) | 72 |
| Eucalyptus haewastowa (spotted gum) | 69 |
| Eucalyptus hemiphloia (canary wood, white box, or gray box) | 48 |

* On account of the unsettled nomenclature of Australian woods, this table gives botanical names, with common names, so far as possible, in parenthesis after the botanical name. Also see note at foot of table, Weight of Various Woods, page 279.

TABLE—(*Continued*)

| Wood | Weight Pounds |
|---|---|
| Eucalyptus largiflorens (slaty gum) | 77 |
| Eucalyptus leucoxylon (iron bark, red flowering, or black iron bark) | 70 |
| Eucalyptus longifolia (wollybutt tree) | 69 |
| Eucalyptus maculata (spotted gum) | 63 |
| Eucalyptus marginata (jarrah) | 54 |
| Eucalyptus melliodora (yellow box) | 69 |
| Eucalyptus microcorys (tallow wood) | 59 |
| Eucalyptus obliqua (messmate, stringy bark) | 57 |
| Eucalyptus pilularis (blackbutt, or flintwood) | 53 |
| Eucalyptus piperita (blackbutt, white stringy bark tree) | 69 |
| Eucalyptus resinifera (mahogany) | 68 |
| Eucalyptus robusta (swamp mahogany) | 67 |
| Eucalyptus rostrata (red gum tree) | 56 |
| Eucalyptus saligna (gray gum) | 61 |
| Eucalyptus siderophloia (iron bark) | 68 |
| Eucalyptus sieberiana (iron bark, gumtop stringy bark, mountain ashes) | 56 |
| Eucalyptus tereticarnis (flooded gum) | 68 |
| Eucalyptus viminalis (manna gum tree, drooping gum, or white gum tree) | 43 |
| Eugenia smithii (myrtle) | 57 |
| Exocarpus cupressiformis (native cherry tree) | 50 |
| Fagus cunninghamii (evergreen beech or native myrtle) | 45 |
| Hakea leucoptera (water tree) | 51 |
| Heterodendron oleifolium | 53 |
| Lomatia fraseri | 42 |
| Melalenca decussata | 59 |
| Melalenca parviflora | 62 |
| Myporum insulare | 51 |
| Myrsine variabilis | 45 |
| Panax murrayi (palm panax) | 22 |
| Pimelea microcephala | 55 |
| Pittosporum bicolor (white wood) | 48 |
| Pomaderris apetala (hazel) | 48 |
| Prostanthera lasianthas (mint tree) | 51 |
| Santalum acuminatum (native peach or quandong) | 52 |
| Santalum persicarium (native sandalwood) | 47 |
| Senecio bedfordii (native dogwood) | 56 |
| Syncarpia laurifolia (turpentine) | 63 |
| Tristania conferta (brush or white box) | 67 |
| Tristania nerifolia (water gum) | 63 |
| Viminaria denudata | 39 |

## WEIGHT OF 1 CU. FT. OF INDIAN WOODS

(*Berkley-Clark*)

| Wood | Weight Pounds | Wood | Weight Pounds |

## WEIGHT OF AMERICAN TIMBERS

| Wood | Specific Gravity | Weight per Cubic Foot Pounds | Weight per Foot Board Measure Pounds | Remarks |
|---|---|---|---|---|
| California redwood .... | .39 | 24.16 | 2.01 | The weights given are the averages of a large number of determinations for commercially dry lumber containing less than 15% of moisture. The weights of unseasoned green lumber will be from 20 to 40 % greater. Green oak is commonly taken to weigh 5 lb. per running foot board measure. |
| California spruce....... | .40 | 24.97 | 2.08 | |
| Cedar................ | .37 | 23.10 | 1.93 | |
| Chestnut............. | .66 | 41.20 | 3.43 | |
| Cypress.............. | .46 | 28.72 | 2.39 | |
| Douglas fir........... | .51 | 31.84 | 2.65 | |
| Hemlock............. | .40 | 24.97 | 2.08 | |
| Red pine (Norway pine) | .50 | 31.31 | 2.60 | |
| Short-leaf yellow pine... | .51 | 31.84 | 2.65 | |
| Southern, long-leaf, or Georgia yellow pine.... | .61 | 38.08 | 3.17 | |
| Spruce and eastern fir.. | .40 | 24.97 | 2.08 | |
| White oak............. | .80 | 49.94 | 4.16 | |
| White pine............ | .38 | 23.72 | 1.98 | |

## WEIGHT OF 1 SQ. FT. OF BUILDING MATERIALS

| Name of Material | | Average Weight Pounds | Name of Material | | Average Weight Pounds |
|---|---|---|---|---|---|

*Anthracite increases about 75% in bulk when broken to any market size; 1 T. loose, averages from 38 to 46 cu. ft.

†A heaped bushel, loose, weighs about 74 lb., and 1 T. occupies from 43 to 48 cu. ft. Bituminous coal, when broken, occupies 75% more space than in the solid.

‡A heaped bushel, loose, weighs from 35 to 42 lb.; 1 T. occupies 80 to 97 cu. ft.

| Block coal, Indiana............. | 1.27 | 79.4 | .956 |

To Mr. Irving A. Stearns, mining engineer and former general superintendent of the Pennsylvania Railroad Co.'s Coal Department, we are indebted for the following summary of tests made by the mining engineers of this company. Although these tests were made 25 yr. ago, they are still of value as

## WEIGHT OF SUSQUEHANNA COAL CO.'S WHITE ASH ANTHRACITE

| Size | Size of Mesh, in Inches | | Weight per Cubic Foot Pounds | Cubic Feet From 1 Cubic Foot of Solid |
|---|---|---|---|---|
| | Over | Through | | |
| Lump.................. | 4½ to 9 | | 57 | 1.614 |
| Broken................ | 2½ to 2⅞ | 3¼ to 4½ | 53 | 1.755 |
| Egg.................. | 1⅞ to 2¼ | 2½ to 2⅞ | 52 | 1.769 |
| Large stove............ | 1¼ to 1⅞ | 1⅞ to 2¼ | 51½ | 1.787 |
| Small stove............ | 1 to 1¼ | 1¼ to 1⅞ | 51½ | 1.795 |
| Chestnut.............. | ⅝ to ⅞ | 1 to 1¼ | 51 | 1.804 |
| Pea.................. | ⅜ to ⅝ | ⅝ to ⅞ | 50¾ | 1.813 |
| No. 1 buckwheat....... | 3/16 to ⅜ | ⅜ to ⅝ | 50¾ | 1.813 |
| No. 2 buckwheat....... | | 1/16 to ⅜ | 50¾ | 1.813 |

giving the weight of anthracite, but the sizes corresponding to the different grades are not now in use. Sizes of anthracite should be taken from the table Sizes of Prepared Anthracite. These determinations showed an average value for the specific gravity of the coal from the various seams upon this

company's property of 1.4784, together with an average weight per cubic foot of coal in the solid of 92.5 lb.

## CONTENTS OF HORIZONTAL COAL SEAMS*

| Thickness of Seam | | Lignite† | Bituminous† | Anthracite† |
|---|---|---|---|---|
| Feet | Inches | Tons per Acre | Tons per Acre | Tons per Acre |
| | 1 | 141.32 | 152.62 | 151.41 |
| | 2 | 282.63 | 305.24 | 302.82 |
| | 3 | 423.95 | 457.87 | 454.23 |
| | 4 | 565.27 | 610.49 | 605.64 |
| | 5 | 706.58 | 763.11 | 757.06 |
| | 6 | 847.90 | 915.73 | 908.47 |
| | 7 | 989.22 | 1,068.35 | 1,059.88 |
| | 8 | 1,130.54 | 1,220.98 | 1,211.29 |
| | 9 | 1,271.85 | 1,373.60 | 1,362.70 |

| 10 | 0 | 16,958.03 | 18,314.67 | 18,169.32 |

Mr. Robert A. Quin, Manager Susquehanna Coal Co., has very kindly furnished the two following tables. The first shows the present (1914) sizes of anthracite, and the second shows the number of cubic feet per ton occupied by each of these sizes, according to the region in which it is mined.

## SIZES OF PREPARED ANTHRACITE

| Size | Through | | Over | |
|---|---|---|---|---|
| | Square Inches | Round Inches | Square Inches | Round Inches |
| Lump...................... | | | 5¾ | 6½ |
| Steamboat................. | 5¾ | 6½ | 4 | 4½ |
| Broken.................... | 4 | 4½ | 2¾ | 3¼ |
| Egg....................... | 2¾ | 3¼ | 2 | 2¼ |
| Stove..................... | 2 | 2¼ | 1¾ | 1⅞ |
| Chestnut.................. | 1¾ | 1⅞ | ⅞ | 1 |
| Pea....................... | ⅞ | 1 | 9/16 | ⅝ |
| No. 1 Buckwheat........... | 9/16 | ⅝ | ¼ | ⅜ |
| No. 2 Buckwheat........... | ¼ | ⅜ | ⅛ | 3/16 |
| No. 3 Buckwheat........... | ⅛ | 3/16 | 1/16 | 3/32 |

* This table is based on the average specific gravity of American coals.
† The contents of the bituminous coal and lignite is given in tons of 2,000 lb.; the contents of anthracite seams, in tons of 2,240 lb.

## CUBIC FT. IN 1 T. OF ANTHRACITE BROKEN IN TRADE SIZES

\* The contents of pipes or cylinders in gallons or pounds are to each other as the squares of their diameters. Thus, a pipe 9 ft. in diameter will contain 9 times as much as a 3-ft. pipe, or 4 times as much as a 4½-ft. pipe.

## STANDARD DIMENSIONS OF WROUGHT-IRON WELDED PIPES

The threads have an angle of 60°, with flat tops and bottoms, and are of the following proportions:

*Notation of Letters, All Dimensions in Inches*

$D$ = outside diameter of screw;
$d$ = diameter of root of thread, or of hole in nut;
$p$ = pitch of screw;
$t$ = number of threads per inch;
$f$ = flat top and bottom;
$o$ = outside diameter of hexagon nut or bolt head;

$i$ = inside diameter of hexagon, or side of square nut or bolt head;
$s$ = diagonal of square nut or bolt head;
$h$ = height of rough or unfinished bolt head.

The height of a finished nut or bolt head is made equal to the diameter $D$ of the screw.

$$p = \frac{\sqrt{16D+10}-2.909}{16.64}, \qquad t = \frac{1}{p} \qquad s = 1.414i$$

$$d = D - \frac{1.299}{t} \qquad i = \frac{3D}{2} + \frac{1}{8} \qquad o = 1.155i \qquad f = \frac{p}{8}$$

## WEIGHT OF 1 LIN. FT. OF FLAT WROUGHT IRON*

# TIMBER AND BOARD MEASURE

## TIMBER MEASURE

**Volume of Round Timber.**—The cubic contents of a round log are those of a cylinder of the same dimensions. As logs usually taper throughout their length, the diameter taken is the mean of the two end diameters. The cubic contents of a cylinder are expressed by the formula, $\frac{\pi d^2}{4} l = \frac{\pi d}{4} dl$. From this it is possible to deduce, for field use, the following:

**Rule.**—*The number of cubic feet in a round log is equal to one-quarter of the mean girth* $\left(\text{circumference or } \frac{\pi d}{4}\right)$ *multiplied by the mean diameter multiplied by the length. If, as is usually the case, the girth and diameter are given in inches, the result obtained must be divided by 144.*

*Multiply by .95 for weight of cast iron; by 1.02 for weight of steel; by 1.16 for copper; by 1.09 for brass; by 1.48 for lead.

When the accompanying table of quarter girths is used, it is only necessary to measure the circumference of each end of the log and divide the sum by 2, for the mean girth. Opposite one-quarter of this mean girth, find the area in feet. This multiplied by the length of the log, gives the cubic contents in feet.

EXAMPLE.—The circumferences of a 20-ft. log are 48 and 60 in., respectively. What is the cubic contents of the log?

SOLUTION.— $(48 + 60) \div 2 = 54 =$ mean girth. $54 \div 4 = 13\frac{1}{2} =$ one-quarter girth. The area corresponding to a quarter girth of $13\frac{1}{2}$ in. is 1.26 sq. ft. Hence, $1.26 \times 20 = 25.20$, number of cubic feet in the log.

## TABLE OF QUARTER GIRTHS

| Quarter Girths Inches | Area Feet | Quarter Girths Inches | Area Feet | Quarter Girths Inches | Area Feet |
|---|---|---|---|---|---|
| 6 | .250 | $12\frac{1}{4}$ | 1.04 | 19 | 2.50 |

## BOARD MEASURE

The unit of board measure (B. M.) is the *board foot*, which is the contents of a board 1 ft. square and 1 in. thick. When calculating board feet all thicknesses under 1 in. are counted as if 1 in., while all over 1 in. are counted at their exact value. Thus, a $\frac{3}{4}$-in. plank is counted as a 1-in. plank, and a $1\frac{1}{2}$-in. plank as $1\frac{1}{2}$ in. When estimating the number of board feet that should be cut from a log, numerous rules have been devised, but the one in most general use is known as *Doyle's, Connecticut River,* or *Scribner's rule*; it is as follows:

**Rule.**—*The diameter of the small end of the log, inside the bark, is first measured. From this diameter, 4 in. are deducted for slabbing and squaring up. The square of one-fourth of this remainder, multiplied by the length, in feet, will give the resultant board feet.*

**Table of Board Feet.**—The number of feet board measure for 1 ft. in length of planks of all thicknesses, increasing by single inches, up to 12 in., and thence, by each 2 in. up to 24 in., are given in the accompanying table. In the rare cases where the thickness is not an even inch, the value for the board feet may be found by interpolation. For timbers larger than $12 \times 24$, it is necessary to take the board feet of two pieces each one-half the size of the stick under consideration. Thus, the number of board feet in one piece $16 \times 24$ is twice the number of board feet in a piece $8 \times 24$ or in one $16 \times 12$.

To economize space, the values have been carried to the first repeating decimal only, which is marked with a (*). Unless the extension indicated is

made, the final figure should be made 1 greater than in the table; thus, if the figures in the table are 1.6*, this should be used as 1.7; or, better, as 1.67, or 1⅔, because the correct value is 1.66666, repeating indefinitely.

### TABLE OF BOARD FEET

| Depth, Inches | Width of Plank, in Inches | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 |

# HYDROSTATICS

*Hydrostatics* treats of the equilibrium of liquids and of their pressures on the walls of vessels containing them; the science depends on the way in which the molecules of a liquid form a mass under the action of gravity and molecular attraction, the latter of which is so modified in liquids as to give them their state of liquidity. While the particles of a liquid cohere, they are free to slide upon one another without the least apparent friction; and it is this perfect mobility that gives them the mechanical properties considered in hydrostatics.

The fundamental property of hydrostatics is a physical axiom, and on it are based nearly all the principles of hydrostatics; it is as follows:

*When a pressure is exerted on any part of the mass of a liquid, that pressure is transmitted undiminished to all parts of the mass, and in all directions.*

**Equilibrium of Liquids.**—The equilibrium of liquids is a property that can be easily demonstrated, and examples are frequently seen. Thus, if two barrels are connected at the bottom with a pipe, and water is poured in one until it reaches within 1 ft. of the top, the water in the other will be found to have attained the same height.

**Pressure of Liquids on Surfaces.**—The general law governing the pressure of liquids on surfaces is as follows:

**Law.**—*The pressure of a liquid on any surface immersed in it is equal to the weight of a column of the liquid whose base is the surface pressed, and whose height is the perpendicular depth of the center of gravity of the surface below the surface of the liquid.*

The pressure exerted by liquids is independent of the shape or size of the vessel or cavity containing the liquid. The pressure of a liquid against any point of any surface, either curved or plane, is always perpendicular to the surface at that point. At any given depth, the pressure of a liquid is equal in every direction, and is in direct proportion to the vertical depth below the surface.

The weight of 1 cu. ft. of fresh water, at ordinary temperature of the atmosphere, that is, from 32° F. to 90° F., is usually assumed at 62.5 lb. This is a trifle more than the actual weight, but is sufficiently close for most practical purposes.

**To Find Pressure Exerted by Quiet Water Against Side of Gangway or Heading.**—Multiply the area of the side, in square feet, by the perpendicular distance from the surface of the water to a point equidistant between the top and bottom of the submerged heading or gangway, and multiply the product by 62.5. The result will be the pressure, in pounds, exclusive of atmospheric pressure; this latter need not be considered in ordinary mining work.

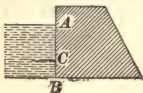
EXAMPLE.—If an abandoned colliery, opened by a slope on a pitch of 25° and 100 yd. long, is allowed to fill with water, what is the average pressure exerted on each square foot of the lower rib of the gangway, assuming that the gangways were driven dead level, and that the length of the slope was measured to a point on the lower rib equidistant between top and bottom of gangway?

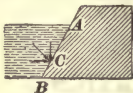
SOLUTION.—Perpendicular height of water is $300 \times \sin 25° = 126.78$ ft. Then, the pressure on each square foot of the lower rib of gangway is $126.78 \times 62.5$ lb., $= 7,923.75$ lb., or over $3\frac{1}{2}$ gross tons. The total pressure exerted along the gangway may readily be found by multiplying 7,923.75 lb. by the number of square feet in the lower rib against which it rests.

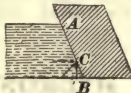
**Pressure Against Dams, Etc.**—To find the total pressure of quiet water against and perpendicular to any surface whatever, as a dam, embankment, or the bottom, side, or top of any containing vessel, water pipe, etc., no matter whether said surface is vertical, horizontal, or inclined; or whether it is flat or curved; or whether it reaches to the surface of the water or is entirely below it, apply the following rule:

**Rule.**—*Multiply the area, in square feet, of the surface pressed by the vertical depth, in feet, of its center of gravity below the surface of the water, and this product by 62.5; the result will be the pressure in pounds.*

Thus, assume that in Figs. 1, 2, and 3 the depth of water in each dam is 12 ft., and the wall or embankment is 50 ft. long. In Fig. 1 the total pressure will equal $12 \times 50 \times 6 \times 62.5 = 225,000$ lb. In Figs. 2 and 3, the walls or embankments, being inclined, expose a greater surface to pressure, say, 18 ft. from $A$ to $B$. Then the total pressure equals $18 \times 50 \times 6 \times 62.5 = 337,500$ lb.







The results obtained are the total pressures without regard to direction. In Fig. 1 the total pressure calculated, or 225,000 lb., is horizontal, tending either to overturn the wall or make it slide on its base. The center of pressure is at $C$, or one-third of the vertical depth from the bottom. In Fig. 2, the pressure is exerted in two directions; one pressure, acting horizontally, tends to overthrow or slide the wall, while the other, acting vertically, tends to hold it in place. In Fig. 3, the pressure is also exerted in two directions; one pressure, acting horizontally, tends to overthrow or slide the wall, while the other tends to lift. So long as the vertical depth of water remains the same, the horizontal pressure remains the same, no matter what inclination is given the wall. Thus, in Figs. 2 and 3, the horizontal pressure is the same as in Fig. 1, or 225,000 lb.

**Distribution of Pressure.**—The total pressure of the water is distributed over the entire depth of the submerged part of the back of the wall, and is least at the top, gradually increasing toward the bottom. But so far as regards the united action of every portion of it, in tending to overthrow the wall, considered as a single mass of masonry incapable of being bent or broken, it may all be assumed to be applied at $C$, which is one-third of the vertical depth from the bottom in Fig. 1, or, what is the same thing, one-third of the slope distance from the bottom in Figs. 2 and 3.

No matter how much water is in a dam or vessel, the pressure remains the same, so long as the area pressed and the vertical depth of its center of gravity below the level surface of the water remains unchanged. Thus, if the water in dam shown in Fig. 1 extended back 1 m., it would exert no more pressure against the wall than if it extended back only 1 ft.

In any two vessels having the same base, and containing the same depth of water, no matter what quantity, the pressures on the bases are equal. Thus, if Figs. 4 and 5 have the same base and are filled with water to the same depth, the pressure on the bases will be equal. This fact, that the pressure on a given

surface, at a given depth, is independent of the quantity of water, is called the *hydrostatic paradox.*

As the pressure of water against any point is at right angles to the surface at that point, props or other strengthening material for the bracing of such structures as a sloping dam, should be so placed as to offer the greatest resistance in a line at right angles to the sloping surface, and these supports should be strongest and closest together at the bottom. For the same reason, the hoops on a circular tank should be strongest and closest at the bottom.

**Transmission of Pressure Through Water.**—Water, in common with other liquids, possesses the important property of transmitting pressure equally in all directions. Thus, if a vessel is constructed

FIG. 4    FIG. 5

FIG. 6

with two cylinders, the area of one being 10 sq. in., and that of the other 100 sq. in., and the vessel is filled with water, as in Fig. 6, and pistons are fitted to the cylinders, a pressure of 100 lb. applied at the smaller will balance 1,000 lb. at the larger. This is the principle of the hydrostatic press. Air and other gaseous fluids transmit pressure equally in all directions, like liquids, but not as rapidly.

**To Find Pressure on Plane Surface at Any Given Depth of Water.**—For pounds per square inch, multiply depth in feet by .434. For pounds per square foot, multiply depth in feet by 62.5. For tons per square foot, multiply

**PRESSURE AT DIFFERENT VERTICAL DEPTHS ALSO TOTAL PRESSURE AGAINST A PLANE 1 FT. WIDE EXTENDING VERTICALLY FROM SURFACE OF WATER TO SAME DEPTHS**

depth in feet by .0279. The pressure per square foot at different depths increases directly as the depths. The total pressure against a plane 1 ft. wide at different depths increases as the square of the depths.

**Pressure of Water in Pipes.**—As water exerts a pressure equally in all directions, it is important that, in pipe lines, the pipe should be sufficiently thick to assure strength enough to resist a bursting pressure. In ordinary practice, the thickness of cast-iron water pipes of different bores is calculated by Mr. J. T. Fanning's formula, given in his Hydraulic Engineering, which is as follows, the thickness and bore being given in inches and the pressure in pounds per square inch:

$$\text{Thickness} = \frac{(\text{pressure} + 100) \times \text{bore}}{.4 \times \text{ultimate tensile strength}} + .333 \times \left(1 - \frac{\text{bore}}{100}\right)$$

This formula, worked out for different heads and different sizes of bore, yields the results given in the accompanying table. In this table, the ultimate tensile strength of cast iron is taken at 18,000 lb. per sq. in. The addition of 100 lb. to the pressure is made to allow for water ram. The valves of water pipes should be closed slowly, and especially as the pipes increase in diameter. If this rule is not observed, the momentum of the water which is suddenly stopped creates a great pressure against the pipes in all directions and throughout the entire length of the line above the valve, even if it is many miles long, and there is danger of the pipes bursting at any point. For this reason, stop-gates are shut by screws, because they prevent any very sudden closing; but in pipes of large diameters, even the screws must be worked very slowly to prevent the pipes bursting.

## THICKNESS OF PIPE FOR DIFFERENT HEADS AND PRESSURES

| Head, in Feet .... | 50 | 100 | 200 | 300 | 500 | 1,000 |
|---|---|---|---|---|---|---|
| Pressure, in Pounds per Square Inch | 21.7 | 43.4 | 86.8 | 130 | 217 | 434 |

**Wooden Pipe.**—The sizes of wooden pipes up to 6 in., and sometimes up to 12 in. in diameter are commonly bored from a single log. The sizes up to 48 in. in diameter are made from a series of staves placed side by side and wrapped with wire, steel bands, etc., and coated with tar or some similar preservative. The sizes given in the accompanying table are made in the factories and shipped to destination. Larger sizes 54-, 60-, 66-, 72-, 78-, 84-, 90-, 96-, 108-, and 120-in. pipes are made on the ground where used from staves of the proper cross-section. As built, the staves break joint at least 24 in. so that they interlock longitudinally, forming a continuous pipe. While being placed, the completed pipe is wrapped with steel wire or bands. For heads up to 400 ft. (173 lb. per sq. in.) wooden pipe has been used for many years and possesses numerous advantages over cast- or wrought-iron pipe. Owing to the smoothness of its interior, its carrying capacity for water is much greater

## STANDARD SIZES OF WOOD PIPE

| Inside Diameter of Pipe Inches | Outside Diameter of Pipe Inches | Weight per Foot 80-lb. Pressure Pounds | Number of Feet a 40-Ft. Car Will Hold |
|---|---|---|---|
| 1½ | 3¾ | 2 | 17,000 |
| 2 | 4¾ | 4 | 11,000 |
| 3 | 6¼ | 6½ | 6,000 |

| 36 | 42½ | 110 | 175 |
| 48 | 54⅜ | 160 | 65 |

than is that of cast or wrought pipe. This difference is estimated to be about 10% in favor of the wooden pipe when it and the iron pipe are new and as much as 30 or 40% when both are old. Wooden pipe is not affected by acid mine water or by electrolysis as is iron pipe, and for these reasons is in much favor in many mines where the head is not too great. The standard thicknesses are made to resist pressures due to 100 ft., 200 ft., 300 ft., and 400 ft. head, or 43 lb., 87 lb., 130 lb., and 173 lb. per sq. in. pressure. In exceptional cases, wooden pipe has been built to work under 700-ft. head, say, under a pressure of 300 lb.

**Compressibility of Liquids.**—Liquids are not entirely incompressible, but they are so nearly so, that for most purposes they may be considered as incompressible. The bulk of water is diminished about $\frac{1}{1000}$ by a pressure of 324 lb. per sq. in., or 22 atmospheres; varying slightly with its temperature. It is perfectly elastic, regaining its original bulk when the pressure is removed.

# HYDRAULICS

## DEFINITIONS

*Hydraulics* treats of liquids in motion, and in this, as in hydrostatics, water is taken as the type. In theory, its principles are the same as those of falling bodies, but in practice they are so modified by various causes that they cannot be relied on except as verified by experiment. The discrepancy arises from changes of temperature that vary the fluidity of the liquid, from friction, the shape of the orifice, etc. When dealing with water only, the first cause need not be considered. In theory the velocity of a jet is the same as that of a body falling from the surface of the water.

**To Find Theoretical Velocity of Jet of Water.**—Let $v$ = velocity, $g$ = acceleration of gravity (32.16 ft.), and $d$ = distance of orifice below surface of water. Then,
$$v = \sqrt{2gd}.$$

EXAMPLE.—The depth of water above the orifice is 64 ft.; what is the velocity?

SOLUTION.—Substituting in the formula 64 for $d$ and 32.16 for $g$,

$$v = \sqrt{2 \times 32.16 \times 64} = 64.16.$$

**To Find Theoretical Quantity of Water Discharged in Given Time.**—Multiply the area of the orifice by the velocity of the water, and that product by the number of seconds.

EXAMPLE.—What quantity of water will be discharged in 5 sec. from an orifice having an area of 2 sq. ft., at a depth of 16 ft.?

SOLUTION.— $2 \times \sqrt{2 \times 32.16 \times 16} = 64.16$ cu. ft., or the amount discharged in 1 sec., and in 5 sec. the amount will be $5 \times 64.16 = 320.8$ cu. ft.

The foregoing rules are only theoretical, and are only useful as foundations on which to build practical formulas.

**Flow of Water Through Orifices.**—The standard orifice, or an orifice so arranged that the water when flowing from it touches only a line, as is the case when flowing through a hole in a very thin plate, is used for the measurement of water. The contraction of the jet, which always occurs when water issues from a standard orifice, is due to the circumstance that the particles of water as they approach the orifice move in converging directions, and that these directions continue to converge for a short distance beyond the plane of the orifice. This contraction causes only the inner corner of the orifice to be touched by the escaping water, and takes place in orifices of any shape, its cross-section being similar to the orifice until the place of greatest contraction is passed. Owing to this contraction, the actual discharge from an orifice is always less than the theoretical discharge.

**Coefficient of Contraction.**—The coefficient of contraction is the number by which the area of the orifice is to be multiplied in order to find the area of the least cross-section of the jet. By experiment, this coefficient has been found to be about .62 (Merriman's "Hydraulics"); or, in other words, the minimum cross-section of the jet is 62% of the cross-section of the orifice.

**Coefficient of Velocity.**—The coefficient of velocity is the number by which the theoretical velocity of flow from the orifice is to be multiplied in order to find the actual velocity at the least cross-section of the jet. This may be taken for practical work as .98; or, in other words, the actual flow at the contracted section is 98% of the theoretical velocity.

**Coefficient of Discharge.**—The coefficient of discharge is the number by which the theoretical discharge is to be multiplied in order to obtain the actual discharge. This has been found by thousands of experiments to be equal to the product of the coefficients of contraction and velocity, and for practical work it may be taken as .61; or, the actual discharge from standard orifices is 61% of the theoretical discharge.

NOTE.—While the coefficients for standard orifices with sharp edges have been determined fairly close, those for the more complicated cases of weirs, and especially for the flow of water through long pipes, are simply the nearest approximation to the truth that it has been possible to obtain. In all cases, the coefficient should be one that has been determined under conditions similar to those in the problem in hand. For instance, it is not practicable to use the coefficient for small pipes in solving problems relating to large ones, or for short pipes in solving problems relating to long ones.

**Suppression of Contraction.**—When a vertical orifice has its lower edge at the bottom of a reservoir, the particles of water flowing through its lower portion move in lines nearly perpendicular to the plane of the orifice, and the contraction of the jet does not form on the lower side. The same thing occurs in a lesser degree when the lower edge of the orifice is within a distance of three times its least diameter from the bottom. The suppression of contraction will occur on the side if it is placed within a distance of three times its least diameter from the side of a reservoir, the suppression of contraction being the greater the nearer the orifice is to the side. By rounding the edge of the orifice sufficiently, the contraction can be completely suppressed, and the discharge can be increased. As stated before, the value of the coefficient of contraction for a standard square-edged orifice is .62, but with a rounded orifice it may have any value between .62 and 1, depending on the degree of rounding. The coefficient of discharge for square-edged orifices has a mean value of .61; this is increased with rounded edges and may have any value between .61 and 1, although it is not probable that values greater than .95 can be obtained except by the most careful adjustment of the rounded edges to the exact curve of a completely contracted jet. A rounded interior orifice is therefore always a source of error when the object of the orifice is the measurement of the discharge.

## GAUGING WATER

Water is sold by two methods; i. e., the flowing unit and the capacity unit. The flowing unit is 1 cu. ft. per sec. In the western part of North America the *miners' inch* has come into use quite largely, while in Australia and New Zealand the cubic foot per second is the common measure; 1 cu. ft. per sec. being 1 *head*, 10 heads of water is 10 cu. ft. per sec., regardless of the actual hydrostatic head under which the water is delivered. Water is sometimes sold for irrigation by the capacity unit, that is, so much land covered to a certain depth, as, for instance, the *acre-foot*, which means that 1 A. has been covered to a depth of 1 ft., or that 43,560 cu. ft. of water has been furnished.

**Miners' Inch.**—The miners' inch may be roughly defined as the quantity of water that will flow in 1 min. through a vertical standard orifice having a section of 1 sq. in. and a head of $6\frac{1}{2}$ in. above the center of the orifice. This quantity equals 1.53 cu. ft., and the mean quantity may be taken at, approximately, 1.5 cu. ft. per min. The laws or customs defining the miners' inch in different districts vary so that the amount of water actually delivered varies from 1.2 to 1.76 cu. ft. per min. The principal reasons for these variations are the methods adopted for measuring the water where large quantities are used; as, for instance, at Smartsville, California, an opening 4 in. deep, 250 in. long, with a head of 7 in. above the top edge, is said to furnish 1,000 miners' inches, while it actually furnishes considerably over 1,000. In other places, the size of the opening for measuring the amounts is restricted, and may actually furnish less than the rated amount. In Montana the common method of measurement was formerly through a vertical rectangle 1 in. high, with a head on the center

### DUTY OF MINERS' INCH

(*Risdon Iron Works, Evans's Elevator Catalogue*)

North Bloomfield Mine

| Years | Amount of Gravel Washed Cubic Yards | Miners' 24-Hour Inches | Grades | Amount Washed per Miners' Inch Cubic Yards | Water Used per Cubic Foot of Gravel Moved Cubic Feet | Height of Bank Feet |

La Grange Mine

| Years | Amount of Gravel Washed Cubic Yards | Miners' 24-Hour Inches | Grades | Amount Washed per Miners' Inch Cubic Yards | Water Used per Cubic Foot of Gravel Moved Cubic Feet | Height of Bank Feet |
|---|---|---|---|---|---|---|
| 1874-76 | 676,968 | 624,745 | 4 in. to 16 ft. | 1.08 | 74.0 | 10 to 48 |
| 1875-76 | 683,244 | 375,155 | 4 in. to 16 ft. | 1.82 | 43.9 | 6 |
| 1874-76 | 284,932 | 207,010 | 4 in. to 16 ft. | 1.37 | 58.0 | 50 to 80 |
| 1875-78 | 459,570 | 302,960 | 4 in. to 16 ft. | 1.52 | 52.0 | 40 to 50 |
| 1880-81 | 329,120 | 203,325 | 4 in. to 16 tt. | 1.57 | 50.0 | 10 to 80 |
| Totals | 2,433,834 | 1,713,195 | | 1.42 | 56.0 | |

of the orifice of 4 in. The number of miners' inches discharged was considered to be the same as the number of linear inches in the length of the orifice; thus, under the given head, an orifice 1 in. deep and 60 in. long could discharge 60 miners' inches.

The State Legislature of Montana has now passed a law defining the miners' inch as the number of gallons of water discharged in a given time, regardless of the character of the openings or methods of measurement. The statement is as follows: "Where water rights, expressed in miners' inches, have been granted, 100 miners' inches shall be considered equivalent to a flow of $2\frac{1}{2}$ cu. ft. per sec. (18.7 gal.), and this proportion shall be observed in determining the equivalent flow represented by any number of miners' inches." If this amount is reduced to cubic feet per minute, it will be found to be equal to a flow of 1.5 cu. ft. per min., which is the value given for the miners' inch.

**Duty or Work Performed by a Miners' Inch of Water.**—Few tests have been made in regard to the duty of a miners' inch of water, but the North Bloomfield mine and the La Grange mine, in California, have carried on a series of experiments extending over several years. At the La Grange mine, the observations were carried on simultaneously upon several different claims, hence parallel dates appear. The following table gives the results of these experi-

| Number of Sluice Heads | Dimensions of Aperture, in Inches | | Depth of Pressure Board Above Top of Aperture Inches |
|---|---|---|---|
| | Width | Depth | |
| 1 | 16 | 1 | $5\frac{1}{2}$ |
| 2 | 16 | 2 | $4\frac{3}{4}$ |
| 3 | 16 | $2\frac{1}{4}$ | $9\frac{1}{16}$ |
| 4 | 16 | $2\frac{3}{8}$ | $10\frac{5}{8}$ |
| 5 | 16 | $3\frac{1}{2}$ | $9\frac{1}{4}$ |
| 6 | 32 | $2\frac{1}{4}$ | $8\frac{5}{8}$ |
| 7 | 32 | $2\frac{1}{2}$ | $9\frac{1}{2}$ |
| 8 | 32 | $2\frac{3}{4}$ | 10 |
| 9 | 32 | 3 | $10\frac{1}{2}$ |
| 10 | 32 | $3\frac{1}{2}$ | $8\frac{3}{4}$ |

ments. In general the duty is governed by the size, capacity, character of pavement, and grade of sluices, together with the supply of water. A heavy grade will compensate for a limited supply. With an abundant supply of water and material, the capacity of the sluices will depend on the character of the material washed, the size and minimum grade of the sluices, and the character of the riffles used. In the North Bloomfield mine the sluices were 6 ft. wide, and 32 in. deep. The riffles were principally blocks (wood), but rock riffles were used in the tail sluices. The larger portion of the material moved was top gravel. In the La Grange mine the sluices were 4 ft. wide and 30 in. deep, and were paved with blocks.

**Sluice Head.**—In Tasmania and the Australian Provinces, water is sold by the sluice head. For the following information relating to Tasmania, we are indebted to Roy Bamford, Esq., South Mt. Cameron, Tasmania.

"The sluice head as leased by mining companies from the Government at a rental of £1 per yr. for each head, amounts to 24 cu. ft. per min. and is measured as follows:

"A Government gauge box for measuring water is 12 ft. long, open on top,

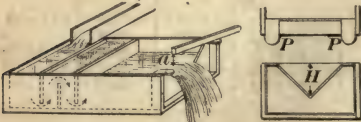
and set truly horizontal. The outlet end of the box is closed with a board 1 in. in thickness with the exception of an aperture, which is always the full width of the gauge box. In all cases, the lower end of the aperture is 2 in. above the bottom of the gauge box. When measuring the discharge


FIG. 1

through the aperture, the water must stand on a level with the top of the

board. When more than ten sluice heads of water are required to be measured, two or more of such gauge boxes shall be used.''

**Gauging by V Notch.**—The right-angled V notch is frequently used for gauging the flow of comparatively small streams. The notch is usually fitted into a box provided with baffle boards, Fig. 1, or, where this is not practicable, the water should be so impounded above the notch as to remove all possibility of surface currents producing a perceptible velocity of approach. The distance $a$ of the surface of the water below the top of the box is taken at a point some distance back from the notch (at least 18 to 20 in.), where the sur-

*1 cu. ft. contains 7.48 U. S. gal.; 1 U. S. gal. weighs 8.34 lb.

face of the water is unaffected by the flow through the notch. The distance $a$, subtracted from the total depth of the notch $H$, gives the head $h$ of the water passing over the notch. The discharge, in cubic feet per second, may be found by the formula

$$Q = .306\sqrt{h^5} = .306h^2\sqrt{h},$$

in which $Q$ = quantity, in cubic feet per minute;
$h$ = head, in inches.

The accompanying table gives the discharge, in cubic feet per minute, through a right-angled **V** notch, as shown in Fig. 1, for heads varying from 1.05 in. to 12 in.

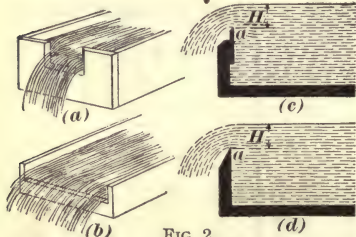

FIG. 2

**Gauging by Weirs.**—A weir is an obstruction placed across a stream for the purpose of diverting the water so as to make it flow through a desired channel, which may be a notch or opening in the weir itself. The term usually applies to rectangular notches in which the water touches the bottom and ends, the opening being a notch without any upper edge. Weirs are of two general classes: *weirs with end contractions*, Fig. 2 (a), and *weirs without end contractions*, as in (b). The crest and edges of the weir with end contractions should be sharp, as shown in (c) and (d). The head of water $H$ producing the flow over the weir should be measured at a sufficient distance from the crest to avoid the effects of the curve of the surface as it flows over the crest. The water above the weir should be motionless, or if it has any perceptible current toward the weir, this should be determined and taken into account in the formula. Fig. 3 illustrates a weir constructed across a small stream for measuring its flow. The head is measured from the stake $E$ some distance back of the weir, the top of the stake being level with the crest of the weir $B$. The discharge over the weir may be calculated from the following formula:

FIG. 3

Let $l$ = length of weir, in feet;
$H$ = head, in feet;
$v$ = velocity with which water approaches weir, in feet;
$h$ = head equivalent to velocity with which water approaches weir;
$c$ = coefficient of discharge;
$Q$ = theoretic discharge, in cubic feet per second;
$Q'$ = actual discharge, in cubic feet per second.

For weirs with end contractions and a velocity of approach, the actual discharge is

$$Q' = 5.347\ cl\sqrt{(H + 1.4h)^3}$$

Where the water has no velocity of approach,

$$Q' = 5.347\ cl\sqrt{H^3}$$

For weirs without end contractions, but with a velocity of approach, the actual discharge is

$$Q' = 5.347\ cl\sqrt{(H + \tfrac{4}{3}h)^3}$$

Where the water has no velocity of approach,

$$Q' = 5.347\ cl\sqrt{H^3}$$

The velocity with which the water approaches the weir may be found by determining the approximate discharge from the stream without any allowance for velocity of approach, and then dividing this discharge, in cubic feet per

second, by the area of the stream, in square feet, where it approaches the weir, which will give the velocity of approach, in feet per second. Having obtained the value of $v$, the equivalent head $h$ may be found by the formula

$$h = .01555v^2$$

As $v$ is small in a properly constructed weir, it is usually neglected unless great accuracy is required.

The values of coefficients of discharge, as determined from experiments, for weirs with end and for weirs without end contractions are given in the accompanying tables. In the first two tables, the values of the coefficients are given in feet and tenths. When only a close approximation is required, it is desired to take all of the measurement in feet and inches. The third table should not be used unless the length of the crest is at least three or four times the depth of water passing over the weir, for if this is not the case, there will be serious errors caused by end contractions.

## COEFFICIENT OF DISCHARGE FOR WEIRS WITH END CONTRACTIONS

## CONVERSION FACTORS

**Cubic Feet Into Gallons.**—1 cu. ft. = 1,728 cu. in. = 1,728 ÷ 231 gal. = 7.4805194 gal.

**Gallons Into Cubic Feet.**—1 U. S. liq. gal. = 231 cu. in. = 231 ÷ 1,728 cu. ft. = .133680555 cu. ft

**Feet per Second Into Miles per Hour.**—1 ft. per sec. = 3,600 ft. per hr. = $\frac{3600}{5280}$, or $\frac{15}{22}$ mi. per hr.

**Miles per Hour Into Feet per Second.**—1 mi. per hr. = 5,280 ft. per hr. = $\frac{5280}{3600}$, or $\frac{22}{15}$ feet per sec.

**Second-Feet per Day Into Gallons.**—1 sec.-ft., or 7.4805194 gal. per sec. for 1 da., or 86,400 sec. = 646,316.87616 gal.

**Millions of Gallons Into Second-Feet per Day.**—1,000,000 gal. per 24 hr. = $\frac{231,000,000}{1,728 \times 86,400}$ cu. ft. per sec., or 1.5472286 sec. ft.

**Second-Feet per Day Into Acre-Feet.**—1 sec.-ft. flow for 1 da. = 86,400 cu. ft. = 86,400 ÷ 43,560 = 1.983473 A.-ft.

**Acre-Feet Into Second-Feet Flow for 24 Hours.**—1 A.-ft. each 24 hr. = 43,560 cu. ft. each 86,400 sec. = 43,560 ÷ 86,400, or $\frac{11}{22}$ sec.-ft. flow for 24 hr.

**Acre-Feet Into Gallons.**—1 A.-ft. = 43,560 cu. ft. (43,560 × 1,728) ÷ 231 = 325,851.428 gal.

**Millions of Gallons Into Acre-Feet.**—1,000,000 U. S. liq. gal., or 231,000,000 cu. in. = 133,680.555 cu. ft. = 133,680.555 ÷ 43,560 = 3.0688832 A.-ft.

**Second-Feet Into Minute Gallons.**—1 cu. ft. contains 1,728 cu. in.; 1 gal. has a capacity of 231 cu. in.; 1 sec.-ft. equals $[(1,728 \div 231) \times 60]$ gal. per min. $= 448.831164$ min.-gal.

**Minute-Gallons Into Second-Feet.**—1 gal. contains 231 cu. in.; 1 cu. ft. contains 1,728 cu. in.; 1 gal. per min. equals $[(231 \div 1,728) \div 60]$ sec.-ft., $= .0022280092$ sec.-ft.

---

# FLOW OF WATER IN OPEN CHANNELS

**Ditches.**—In the case of hydraulic mining and irrigation, water is usually conveyed through ditches. The ditch line should be carefully surveyed and all brush and trees removed, and the underbrush cut away and burned, before beginning to excavate the ditch. The form of ditch and its grade will depend largely on the amount of water to be conveyed and the character of the soil in the section under consideration. As a general rule, the average flow of water in a ditch should not be less than 2 ft. per sec., and under most circumstances should not exceed 4 ft., though in rare cases where the formation is suitable, mean velocities of 5 ft. per sec. are employed. Sand will deposit from a current flowing at the rate of 1½ ft. per sec., and if the current does not have a velocity of at least 2 ft. per sec., vegetation is liable to block the ditch line.

The following letters will be used in the formulas for determining the various factors relating to ditches:

$h$ = difference in level between ends of canal or ditch, or between two points under consideration;

$l$ = horizontal length of portion of canal or ditch under consideration;

$s$ = slope = ratio $\dfrac{h}{l}$ = sine of slope;

$a$ = area of water cross-section in square feet;

$p$ = wet perimeter = portion of outline of cross-section of stream in contact with channel, in feet;

$r$ = hydraulic radius, or hydraulic mean depth = ratio $\dfrac{a}{p}$;

$c'$ = coefficient, depending on nature of surface of ditch;

$c$ = coefficient depending on nature of surface of ditch, as determined by Kutter's formula;

$v$ = mean velocity of flow, in feet per second;

$v'$ = surface velocity of a stream;

$v_b$ = bottom velocity of a stream;

$x$ = bottom or one side of a section the form of which is one-half a regular hexagon, in feet;

$Q$ = quantity of water flowing, in cubic feet per second;

$n$ = coefficient of roughness in Kutter's formula.

**Safe Bottom Velocity.**—The bottom velocity of a stream may be obtained from the average velocity by the formula

$$v_b = v - 10.87\sqrt{rs}$$

The accompanying table gives values of safe bottom and mean velocities, corresponding with certain materials, as given by Ganguillet and Kutter:

### SAFE BOTTOM AND MEAN VELOCITIES OF STREAMS

| Material of Channel | Safe Bottom Velocity $v_b$ Feet per Second | Mean Velocity $v$ Feet per Second |
|---|---|---|
| Soft brown earth | .249 | .328 |
| Soft loam | .499 | .656 |
| Sand | 1.000 | 1.312 |
| Gravel | 1.998 | 2.625 |
| Pebbles | 2.999 | 3.938 |
| Broken stone, flint | 4.003 | 5.579 |
| Conglomerate, soft slate | 4.988 | 6.564 |
| Stratified rock | 6.006 | 8.204 |
| Hard rock | 10.009 | 13.127 |

**Resistance of Soils to Erosion by Water.**—The following resistances of various soils to erosion by water have been selected from the experiments of W. A. Burr:

| Soil | Feet per Second |
|------|------|
| Pure sand resists erosion by flow of | 1.10 |
| Sandy soil, 15% clay, resists erosion by flow of | 1.20 |
| Sandy loam, 40% clay, resists erosion by flow of | 1.80 |
| Loamy soil, 65% clay, resists erosion by flow of | 3.00 |
| Clay loam, 85% clay, resists erosion by flow of | 4.80 |
| Agricultural clay, 95% clay, resists erosion by flow of | 6.20 |
| Clay, resists erosion by flow of | 7.35 |

**Carrying Capacity of Ditches.**—Ditches should never be run full, but should be constructed large enough so that they will carry the desired amount of water when from three-fourths to seven-eighths full. For any given cross-section, the greatest flow will be attained when the hydraulic radius or hydraulic mean depth is equal to one-half of the actual depth of the channel. The cross-section of a ditch or conduit that has the greatest possible carrying capacity is a half circle, and the nearest practical approach to this is a half hexagon. Knowing the cross-section of a ditch, its dimensions may be found by the formula:

$$x = \sqrt{\frac{2a}{2.598}}$$

As the obtuse angle between the side and bottom of the ditch is 120°, the form can be easily laid off. The carrying capacity of ditches generally increases after they have been in use some time, as the ditch becomes lined with a fine scum that closes the pores in the soil and prevents leakage; this may increase the amount by as much as 10%.

**Grade.**—The grade of the ditch must be sufficient to create the desired velocity of flow, and depends largely on the character of the material composing the surface of the ditch. If the surface is smooth, as, for instance, where the ditch is cut through clay or is lined with masonry, the grade can be considerably less than where the surface is rough, or when cut through coarse gravel or when lined with rough stone. In mountainous countries, where the ground is hard, deep narrow ditches with steep grades are generally preferred to larger channels with gentle slopes, as the cost of excavation is considerably less; but steep grades and narrow ditches are suitable only when the banks can resist the rapid flow. In California, grades of from 16 to 20 ft. per mi. are used, and 10 ft. per mi. is quite common. Water channels of a uniform cross-section should have a uniform grade; otherwise, the flow will be checked in places, which will result in deposits of sand or silt in some portions of the ditch, which are liable to cause the banks to be overflowed and the ditch to be ultimately destroyed. When designing any given ditch, the grade is generally assumed to correspond to the formation of the country and the velocity figured from the grade. In case $v$ is found to be so great that it will cut the banks, it will be necessary either to reduce the grade or to change the form of the ditch so as to reduce the velocity.

*Ditch Banks,* when possible, should be composed of solid material, but when necessary to use excavated material care must be taken to see that the material is so placed as to avoid settling and cracking as much as possible. All stumps, roots, etc. should be separated from the material to be used for embankments. If artificial banks are necessary, they should be built of masonry if the expense is not too great; or, the water may be carried across depressions in pipes or flumes. When the character of the material through which the ditch is constructed is not sufficiently firm to resist the desired current velocity, it is necessary to line the ditch. In some locations the ditches are simply smoothed on the inside and lined with from ¾ in. to 1 in. of cement mortar, made up of Portland cement and sharp sand. In other cases, they are lined with dry stonework laid up in order and carefully bonded together. Sometimes the stonework is pointed with cement or mortar on the inside, so as to present a more uniform surface to the flow. In other cases, the sides are simply revetted with stone.

**Influence of Depth on Ditch.**—The depth of the flow in a ditch has considerable influence on the scouring or eroding of the bottom and the banks, owing to the fact that a much greater average velocity can be attained in a deep stream than in a shallow stream, without causing an excessive velocity of the water in contact with the wet perimeter. For this reason, in cases where banks will stand it, it is best to use narrow deep ditches rather than wide flat

ditches, though each location has to be treated in accordance with its own special conditions, and no general rule can be laid down.

**Measuring the Flow of Water in Channels.**—The laws for the resistance to the flow may be expressed by the relation $ha = c'lpv^2$; or

$$v = \sqrt{\frac{h}{c'l} \times \frac{a}{p}} = \sqrt{\frac{l1}{c'} \times s \times r}$$

If $c = \sqrt{\frac{l1}{c'}}$, the formula becomes

$$v = c\sqrt{rs}$$

The coefficient $c$ is usually found by means of Kutter's formula, one form of which is as follows:

$$c = \frac{23 + \frac{1}{n} + \frac{.00155}{s}}{.5521 + \left(23 + \frac{.00155}{s}\right)\frac{n}{\sqrt{r}}}$$

The values for $n$, the coefficient of roughness under various conditions, are given in the accompanying table:

## COEFFICIENT OF ROUGHNESS UNDER VARIOUS CONDITIONS

| Character of Channel | Value of $n$ |
|---|---|
| Clean, well-planed timber | .009 |
| Clean, smooth, glazed iron, and stoneware pipes | .010 |
| Masonry, smoothly plastered with cement, and for very clean, smooth, cast-iron pipe | .011 |
| Unplaned timber, ordinary cast-iron pipe, and selected pipe sewers, well laid and thoroughly flushed | .012 |
| Rough iron pipes and ordinary sewer pipes, laid under usual conditions | .013 |
| Dressed masonry and well-laid brickwork | .015 |
| Good rubble masonry and ordinary rough or fouled brickwork | .017 |
| Coarse rubble masonry and firm, compact gravel | .020 |
| Well-made earth canals in good alinement | .0225 |
| Rivers and canals in moderately good order and perfectly free from stones and weeds | .025 |
| Rivers and canals in rather bad condition and somewhat obstructed by stones and weeds | .030 |
| Rivers and canals in bad condition, overgrown with vegetation and strewn with stones and other detritus, according to condition | .035 to .05 |

As it is quite difficult to obtain the value of $c$ by Kutter's formula, the following three approximate formulas for $v$ are given:

For canals with earthen banks,

$$v = \sqrt{\frac{100,000r^2s}{9r + 35}}$$

If the ditch is lined with dry stonework,

$$v = \sqrt{\frac{100,000r^2s}{8r + 15}}$$

If the ditch is lined with rubble masonry,

$$v = \sqrt{\frac{100,000r^2s}{7.3r + 6}}$$

To find the quantity $Q$ of water flowing through any channel in a given time, multiply the velocity by the area, or $Q = av$.

**Flow in Brooks and Rivers.**—When a stream is so large that it becomes impracticable to employ a weir for measuring its flow, fairly accurate results may be arrived at by determining the velocity of the current at various points

in a carefully surveyed cross-section of the stream, thus determining both $v$ and $a$. The greatest velocity of current occurs at a point some distance below the surface, in the deepest part of the channel. When determining the current velocities in the different portions of a stream, it is frequently advantageous to divide the stream into divisions. This may be accomplished by stretching a wire across and tying strings or rags about the wire at various points. The mean velocity of the current between these points can be determined by current meters, or by floats. The points for observation should be chosen where the channel is comparatively straight and the current uniform. Surface floats may be used, in which case the mean velocity of the point where the float is used may be found as follows: If $v'$ equals the observed velocity, then the mean velocity will be $v = .9v'$.

By taking observations of the velocity of the current in each section of a stream, the amount of water flowing may be determined for each separate section. The total amount of water flowing in the stream will be the sum of the amounts in each section. The average velocity of the entire stream may be found by dividing the total amount of water flowing by the total area of the cross-section of the stream. The correction necessary to reduce surface velocity to mean velocity may be made as follows: Measure off nine-tenths of the ordinary distance, and figure the time as though for the full distance. For instance, if only 90 ft. is employed, the time will be taken and the problem figured as though it were 100 ft., because the mean velocity is only nine-tenths of the surface velocity.

## FLUMES

*Flumes* are used for conveying water when a ditch line would be abnormally long, or when the material to be excavated is very hard. They may be constructed of timber or of metal, but metal flumes are comparatively rare, as piping can be used instead. The line of the proposed flume should be carefully cleared of all standing timber, and the brush burned for at least 20 ft. each side of the flume line to prevent danger from fire. The life of an ordinary flume, which is supported on or constructed of timber, is always short, varying, as a rule, from 10 to 20 yr., depending on whether the flume is allowed to run dry a portion of the year or is always full of water, the care with which it was originally constructed, and the attention paid to repairs.

**Grade and Form of Flumes.**—Flumes are usually set on a much steeper grade than is possible in ditches, the grade frequently being as much as 25 to 30 ft. per mi., and in special cases even more. The result of this is that the carrying capacity of flumes is much greater than that of ditches of the same size.

The form of flume depends largely on the material of which it is constructed. Metal flumes may have a semicircular form, while wooden flumes are either rectangular or **V**-shaped. The former is used almost exclusively for conveying water, and the latter quite extensively for fluming timber or cord wood from the mountains to the shipping point in the valley.

*Timber flumes* should be so constructed that the water will meet with but small resistance, and the bottom and side should be enclosed in a frame of timbers so braced or secured that there is no possible chance of the sides spreading or lifting from the bottom, and thus causing leakage. As a rule, all mortised-and-tenoned joints should be avoided in flume construction. Fig. 1 shows a timber flume in which no joints are cut; the bottoms of the posts are kept in place by stringers spiked on the sills and the tops are tied together by pieces bolted on. Fig. 2 shows a construction in which the posts are let into the sills and

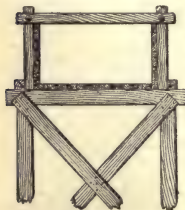

FIG. 1

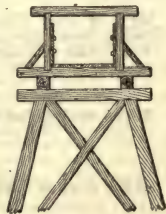

FIG. 2

supported by diagonal braces. The ties across the top of the posts are also notched to receive the upper ends of the posts. As a rule, these ties are only placed on every third or fourth frame, the diagonal braces being depended on to hold the other posts in place. The joints between the planking may be battened on the inside with strips of ½-in. lumber, 4 or 5 in. wide, or the edges

of the planking may be dressed and painted before they are put together, so as to form a tight joint.

**Connection With Ditches.**—Where flumes connect with ditches or dams, the posts for several boxes should be made longer, so that they may receive another sideboard to prevent the water from splashing over the sides. The flume should also be widened out or flared, both at its entry and discharge ends. Where the flume passes through a bank of earth, an outer siding may be nailed on the outside of the posts, to protect the flume from rotting.

**Trestles.**—Where flumes are carried on trestles, the individual frames supporting the flume are usually placed on heavy stringers, which in turn are supported upon trestle bents from 12 to 16 ft. apart, the frames supporting the flume being placed about 4 ft. apart.

**Curves.**—Where flumes are laid around curves, the outer edge of the flume should be elevated so as to prevent splashing and to cause the flowing water to have a uniform depth across the width of the flume. It is impossible to give any definite rule as to the amount that the outer edge of the flume should be raised, but this is usually accomplished by judging the amount when the flume is first constructed, and correcting this by wedging up after the water is flowing. The individual boxes of the flume may have to be cut into two or three portions on curves, and at times the side planks are sawed partly through, so as to enable them to be bent to the desired curve.

**Waste Gates.**—Waste gates should be placed every $\frac{1}{2}$ mi., to empty the flume for repairs, or in case of accident. They are also useful for flushing snow out of a flume. In snowy regions, flumes are frequently protected by sheds over their exposed portions.

**Flow of Water Through Flumes.**—As smooth wooden surfaces offer considerably less resistance to the flow of water than earth or stone canals, the coefficients must necessarily be somewhat reduced, and the following formula is useful in giving the flow of water through flumes:

$$v = \sqrt{\frac{100,000r^2s}{6.6r + 0.46}}$$

That flumes may have their full carrying capacity, they have to be of sufficient length to get the water in motion, or, as it is technically expressed, "to put the water in train." It is largely on this account that flumes have to be made of a larger cross-section at both the entrance and the exit.

In cold countries it may be best to construct the flume narrower than it is deep, as in cold weather the ice in the narrow flume freezes a crust entirely across the surface, thus protecting the water from further action of the elements and frequently prolonging the flow through the flume for several weeks, while wide shallow flumes will not freeze on the surface so quickly, but will freeze in from the bottom and sides until they are practically a solid mass of ice.

When a flume is laid on the ground along a bank, it should be laid as close to the bank as possible, so as to protect it from snow or landslides, and so that in the winter the snow will drift in under and behind it, thus preventing the circulation of the air about the flume. This will protect the flume, and may prolong the flow for some time after cold weather sets in.

# TUNNELS

*Tunnels* are sometimes used for conveying water, in connection with flume or ditch lines. Where a tunnel is unlined, it is best to give the roof the shape of the Gothic arch, because this stands better and resists scaling to a greater extent than the round arch, which usually scales off until it has the form of the Gothic arch. If tunnels are to be used as water conduits, without lining, care should be taken to make the inside of the tunnel as smooth as possible. In some cases, in order to increase the carrying capacity, the tunnel has been lined with wooden-stave pipe, backed with concrete, the pipe requiring no metal bands, but depending on the concrete to keep it in place. When such linings are employed, it is not practicable to have them exposed to the alternate action of the water and the atmosphere; hence, the tunnel should be kept continually full of water. To accomplish this, the tunnel may be dropped below the grade of the ditch or flume line, so that it is always under a slight hydrostatic pressure, and even if the water is turned off from the line, the tunnel will remain full of water, the same as an inverted siphon. Sometimes tunnels are lined with cement, being given either a circular or oval form, or they may have a flat bottom, with flat sides and an arched roof. The cement

may be placed directly on the country rock composing the walls of the tunnel or the tunnel may be lined with brick or stone, and then cemented on the inside.

**Flow Through Tunnels.**—The flow of water through tunnels, when they are only partly filled, is calculated by the formulas for flow in open channels, while in the case of lined tunnels that are run full, the flow is calculated by formulas for calculating the flow through pipes.

# FLOW THROUGH PIPES

**Hydraulic Gradient.**—If a pipe of uniform cross-section is connected with a reservoir, and water is allowed to discharge through its open end, the pressure on the pipe at any point is equal to the vertical distance from the center of the pipe at that point to an imaginary line, called the *hydraulic gradient* or *hydraulic grade line*. This is a line drawn from a point slightly below the surface of the

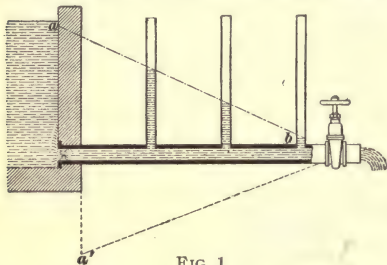

FIG. 1

water in the reservoir to the outlet of the pipe, as *ab*, Fig. 1. The distance from the surface of the water to the point *a* is equal to the head lost in overcoming the friction at the entrance to the pipe, and is rarely over 1 ft. A pipe laid along the line *ab* will carry exactly the same amount of water as when laid horizontally, as shown, but there will be practically no pressure tending to burst the pipe at any point along this line; while if it is laid along the line from the point *a'* (the reservoir being made deeper), it will still deliver exactly the same amount of water, but the pressure tending to burst the pipe will be greatly increased. In order that a pipe may have a maximum discharge, no point in the line must rise above the hydraulic gradient; it makes no difference in the discharge how far below the gradient it may fall.

In Fig. 2, the pipe rises above the hydraulic gradient *ac*; in this case a new hydraulic gradient *ab* must be established and the flow calculated for this head. The pipe *bc* simply acts to carry off the water delivered to it at *b*. If the upper side of the pipe is open at the point *b*, the water will have no tendency to escape, but, on the contrary, air will probably enter and the pipe flow only partly full from *b* to *c*.

**Flow in Pipes.**—Darcy, a French engineer, made a series of experiments on different diameters of cast-iron pipe, with different degrees of internal roughness, from which he calculated a series of formulas. The following are some of these formulas, as arranged by the late E. Sherman Gould, C. E., E. M. Darcy found that the character of the inside surface of the pipe played a very important part in its discharge, and he deduced a formula and determined a series of coefficients for it, but

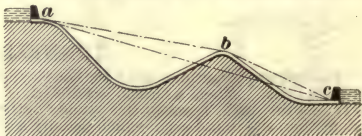

FIG. 2

Mr. Gould calls attention to the fact that the coefficients for pipes from 8 to 48 in. in diameter practically cancel the numerical factor employed in Darcy's formula, and that a slightly different factor applies to pipes from 3 to 8 in., so that the following simple formulas, in which the factors given apply, may be obtained:

$$Q = \text{discharge, in cubic feet per second;}$$
$$q = \text{discharge, in U. S. gallons per minute;}$$
$$D = \text{diameter of pipe, in feet;}$$
$$d = \text{diameter of pipe, in inches;}$$
$$H = \text{total head, in feet;}$$
$$h = \text{head per 1,000 ft.;}$$
$$V = \text{velocity, in feet per second.}$$

*Pipes Between 3 and 8 In. in Diameter*

Rough inside surface, $Q = .89\sqrt{D^5h} = .89D^2\sqrt{Dh}$; $V = 1.13\sqrt{Dh}$

Smooth inside surface, $Q = .89\sqrt{2D^5h} = 1.25D^2\sqrt{Dh}$; $V = 1.6\sqrt{Dh}$

*Pipes Above 8 In. in Diameter*

Rough inside surface, $Q = \sqrt{D^5h} = D^2\sqrt{Dh}$; $V = 1.27\sqrt{Dh}$

Rough inside surface, d in inches, $Q = \dfrac{d^2}{288}\sqrt{\dfrac{dh}{3}}$

Smooth inside surface, $Q = 1.4\sqrt{D^5h} = 1.4D^2\sqrt{Dh}$; $V = 1.78\sqrt{Dh}$

As a rule, it is best to calculate any pipe line by the formula for pipes having a rough internal surface, for if this is not done the results are liable to be disappointing, as all pipes become more or less rough with use.

**Eytelwein's Formula for Delivery of Water in Pipes:**

$D$ = diameter of pipe, in inches;
$H$ = head of water, in feet;
$L$ = length of pipe, in feet;
$W$ = water discharged per minute, in cubic feet.

$$W = 4.71\sqrt{\frac{D^5H}{L}} \qquad D = .538\sqrt[5]{\frac{L \times W^2}{H}}$$

**Hawksley's Formula:**

$G$ = number of gallons delivered per hour;
$L$ = length of pipe, in yards;
$H$ = head of water, in feet;
$D$ = diameter of pipe, in inches.

$$D = \tfrac{1}{15}\sqrt[5]{\frac{G^2L}{H}} \qquad G = \sqrt{\frac{(15D)^5H}{L}}$$

**Neville's General Formula:**

$v$ = velocity, in feet per second;
$r$ = hydraulic mean depth, in feet;
$s$ = sine of inclination, or total fall divided by total length

$$v = 140\sqrt{rs} - 11\sqrt[3]{rs}$$

In cylindrical pipes, $v \times 47.124d^2$ = discharge per minute, in cubic feet, or $v \times 293.7286d^2$ = discharge per minute in gallons, $d$ being the diameter of the pipe in feet.

**Comparison of Formulas.**—The various formulas for velocity are as follows:

$R$ = mean hydraulic depth, in feet = area ÷ wet perimeter = $\dfrac{d}{4}$ for circular section of pipe;

$S$ = sine of slope = $\dfrac{H}{L}$;

$v$ = velocity, in feet per second;
$d$ = diameter of pipe, in feet;
$L$ = length of pipe, in feet;
$H$ = head of water, in feet.

Prony, $\qquad v = 97.05\sqrt{RS} - .08 \qquad v = 99.88\sqrt{RS} - .154$

Eytelwein, $\qquad v = 50\sqrt{\dfrac{dH}{L + 50d}}$

Eytelwein, $\qquad v = 108\sqrt{RS} - .13$

Hawksley, $\qquad v = 48\sqrt{\dfrac{dH}{L + 54d}}$

Neville, $\qquad v = 140\sqrt{RS} - 11\sqrt[3]{RS}$

Darcy, $\qquad v = C\sqrt{RS}$

For the value of $C$ see the following table. The maximum value of $C$ for very large pipes is 113.3.

Kutter, $\qquad v = C\sqrt{RS}$

in which $\qquad C = \dfrac{181 + \dfrac{.00281}{S}}{1 + \dfrac{.026}{\sqrt{d}}\left(41.6 + \dfrac{.00281}{S}\right)}$

Weisbach, $$h = \frac{L}{r}\left(.0036 + \frac{.0043}{\sqrt{v}}\right)\frac{v^2}{2g},$$

in which $h$ = head necessary to overcome friction in the pipe;
$r$ = mean radius of pipe, in feet;
$g$ = gravity = 32.2.

Darcy, $$h = \frac{.02L}{d}\left(1 + \frac{1}{12d}\right)\frac{v^2}{2g}$$

### VALUE OF C IN DARCY'S FORMULA

Diameter of Pipes, in Inches

| $\frac{1}{2}$ | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 12 | 14 | 16 | 18 | 20 | 22 | 24 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|

Value of $C$.

| 65 | 80 | 93 | 99 | 102 | 103 | 105 | 106 | 107 | 108 | 109 | 109.5 | 110 | 110.5 | 110.7 | 111 | 111.5 | 111.5 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|

**Loss of Head in Pipe by Friction.**—In each 100 ft. in length the loss of head, by friction, in pipes of different diameters, when discharging various quantities of water per minute is given in the accompanying table, which has been prepared by the Pelton Water Wheel Co.

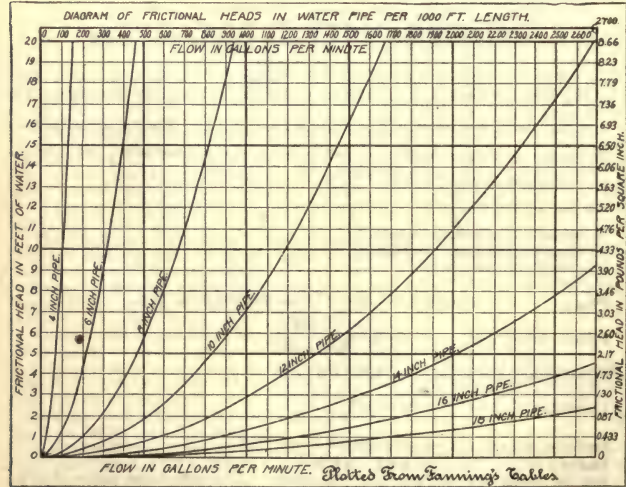

FIG. 3

EXAMPLE.—Having 200-ft. head and 600 ft. of 11-in. pipe, carrying 119 cu. ft. of water per minute, what is the effective head?

SOLUTION.—In right-hand column, under 11-in. pipe, find 119 cu. ft. Opposite this will be found the coefficient of friction for this amount of water, which is .444. Multiplying this by the number of hundred feet of pipe, which

is 6, gives 2.66 ft., which is the loss of head. Therefore, the effective head is $200 - 2.66 = 197.34$.

The following formula, deduced by William Cox, gives practically the same results as the accompanying table, and will be found useful in many instances:

$$F = \frac{L}{1,000D}(4V^2 + 5V - 2),$$

in which
$F =$ friction head;
$L =$ length of pipe, in feet;
$D =$ diameter of pipe, in inches;
$V =$ velocity, in feet per second.

The diagram shown in Fig. 3 gives the frictional heads in 1,000 ft. of water pipe. It shows the flow, in gallons per minute, of the common sizes and gives the frictional heads in both feet of water and pounds per square inch.

**Friction of Knees and Bends.**—To obtain the friction of knees and bends, the following formulas may be taken as giving close approximate results. It is well to bear in mind that right angles should be avoided whenever possible, and that bends should be made with as large a radius as circumstances will allow. The position of the angle $A$ is shown in Fig. 4.

Let $A =$ angle of bend or knee with forward
line of direction;
$V =$ velocity of water, in feet per second;
$R =$ radius of center line of bend;
$r =$ radius of bore of pipe (or $\frac{1}{2}$ diameter);
$K =$ coefficient for angles of knees;
$L =$ coefficient for curvature of bends;
$H =$ head of water, in feet, necessary to
overcome friction of bends, or knees.
$H = .0155V^2K.$

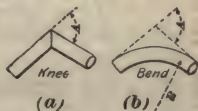

FIG. 4.

The value of $K$ is as follows for different angles:

| $A°$ | $20°$ | $40°$ | $60°$ | $80°$ | $90°$ | $100°$ | $120°$ |
|---|---|---|---|---|---|---|---|
| $K$ | .046 | .139 | .364 | .74 | .98 | 1.26 | 1.86 |

For bends,

$$H = .0155V^2\left(\frac{A}{180}L\right)$$

Values of $L$ for various ratios of the radius of bend to radius of bore:

| When $\frac{r}{R} =$ | .1 | .2 | .3 | .4 | .5 | .6 | .7 | .8 | .9 | 1.0 |
|---|---|---|---|---|---|---|---|---|---|---|
| Circular section $L$ | .131 | .138 | .158 | .206 | .294 | .44 | .66 | .98 | 1.4 | 2.0 |
| Rectangular section $L$ | .124 | .135 | .18 | .25 | .4 | .64 | 1.01 | 1.55 | 2.3 | 3.2 |

## RELATIVE QUANTITIES OF WATER DELIVERED IN 24 HOURS, IN 1 HOUR, AND IN 1 MINUTE

| Gal. in 24 Hr. | Gal. in 1 Hr. | Gal. in 1 Min. | Gal. in 24 Hr. | Gal. in 1 Hr. | Gal. in 1 Min. | Gal. in 24 Hr. | Gal. in 1 Hr. | Gal. in 1 Min. |
|---|---|---|---|---|---|---|---|---|
| 2,500,000 | 104,166.6 | 1,736.0 | 650,000 | 27,083.3 | 451.3 | 150,000 | 6,250.0 | 104.1 |

## RESERVOIRS

When selecting a site for a reservoir, the following points should be observed:

1. A proper elevation above the point at which the water is required.

2. The total supply available, including observations as to the rainfall and snowfall.

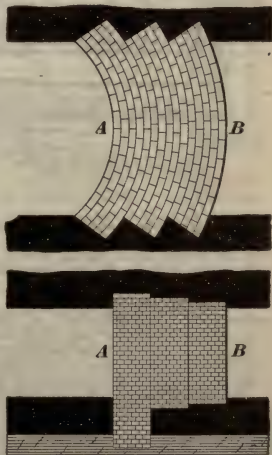
3. The formation and character of the ground, with reference to the amount of absorption and evaporation.

The most desirable formation of ground for a reservoir site is one of compact rock, like granite, gneiss, or slate; porous rocks, like sandstones and limestones, are not so desirable. Steep bare slopes are best for the country surrounding a reservoir, as the water escapes from them quickly. The presence of vegetation above the reservoir causes a considerable amount of absorption; but, at the same time, the rainfall is usually greater in a region covered with vegetation than in a barren region, hence the streams have a more uniform flow. A reservoir must be made large enough to hold a supply capable of meeting the maximum demand. The area of a reservoir should be determined, and a table made showing its contents for every foot in depth, so that the amount of water available can always be known.

## MINE DAMS

Dams may be constructed in mines to isolate a portion of the workings so that they can be flooded to extinguish fires, or, where an extremely wet formation has been penetrated, they may be constructed to prevent the water flowing into the workings. Mine dams should be of sufficient strength to resist any column of water that will be likely to come against them. The dam should be arched toward the direction from which the pressure comes, and should be given a good firm bearing in both walls and in the floor and roof. Fig. 1 illustrates a brick dam that was constructed in Kehley's Run Colliery, at Shenandoah, Pennsylvania, to isolate a portion of the seam so that it might be flooded to extinguish a mine fire. This is one of the largest mine dams that has ever been constructed. It is composed of three brick arches, each having a thickness of 5 ft., placed one against the other so that they act as one solid structure. The gangway at this point is about 20 ft. wide, and the distance to the next upper level is about 119 ft. It was intended that this should be the maximum head of water that the dams would ever have to resist, though they were made sufficiently strong to resist a head of water reaching to the surface. The separate walls were constructed one at a time, and the cement allowed to set before the next wall was placed. The back wall was carried to a greater depth and height than the others, so as to make sure of the fact that all slips or partings had been closed. The total pressure upon the dam when the water was in the mine was about 70,000 lb. per sq. ft.

FIG. 1

Dams constructed to permit the flooding of a mine usually require no passages through them, but where dams are constructed to confine the water to certain parts of the workings, and so reduce pumping charges, it may be necessary to provide both manways and drain pipes through the dams. Fig. 2 illustrates a plan and cross-section of a dam in the Curry Mine, at Norway, Michigan, constructed to keep out of the mine workings the water that came from some exploring drifts. As originally constructed, it was a sandstone dam 10 ft. thick and arched on the back face with a radius of 6 ft. A piece of 20-in. pipe provided a manway through the masonry and was held in place


by three sets of clamps and bolts passing through the stonework. A 5-in. drain pipe was also carried through the dam and secured by clamps. When the pressure came upon the dam it was found to leak, the water was drained off and a 22-in. brick wall built 2 ft. 4 in. back of the dam, the space between being filled with concrete, and the manway and drain pipe extended through the brick wall. Before closing the drain pipe, horse manure was fastened against the face of the brick wall by means of a plank partition. After this

the manway and drain pipe were closed, and when the pressure came on, the dam was found to leak a small amount, but this soon practically ceased, showing that the manure had closed the leaks. A gauge in the head of the manway on this dam showed a pressure of 211 lb., which corresponded to a static head of 640 ft. of water. The total pressure against the dam was something over 800 T., which it successfully resisted.

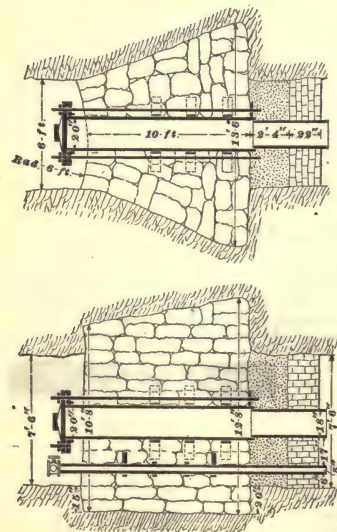
Dams are now successfully made of concrete, which may be used alone or as a support to and surrounding an inner framing of wooden or steel beams, steel rods, etc. The roof and floor as well as the two ribs should be notched deeply so that the dam on all four sides may have ample bearing in order that it may not be bodily pushed forwards by the weight of the water behind it.

## OUTSIDE DAMS

Dams are used for retaining water in reservoirs, for diverting streams in mining, and for storing débris coming from coal washeries in cañons or narrow valleys.

Foundations for dams must be solid to prevent settling, and water-

**Fig. 2**

tight to prevent leakage under the base of the dam. Whenever possible, the foundation should be solid rock. Gravel is better than earth, but when gravel is employed it will be necessary to drive sheet piling under the upper toe of the dam, to prevent water from seeping through the formation under the dam. Vegetable soil should be avoided, and all porous material, such as sand, gravel, etc. should be stripped off until hard pan or solid rock is reached. In case springs occur in the area covered by the foundation of the dam, they must be traced; and if they originate on the upper side their flow must be confined to that side of the dam, so that they will have no tendency to become passageways for water from the upper to the lower face of the dam, thus providing holes that may ultimately destroy the entire foundation of the structure.


**Wooden Dams.**—Wooden dams are constructed of round, sawed, or hewn logs. The timbers are usually at least 1 ft. square, or, if round, from 18 to 24 in. in diameter. A series of cribs from 8 to 10 ft. square are constructed by building up the logs in log-house fashion and securing them together with tree-nails. The individual cribs are secured to one another with treenails or by means of bolts. The cribs are usually filled with loose rock to keep them in place, and in many cases are secured to the foundation by means of bolts. A layer of planking on the upper face of the dam makes it watertight, and when the spillway is over the crest of the dam the top of the cribs must be planked. In most cases, it is also necessary to provide an apron for the water to fall on. The apron may be set on small cribs, or on timbers projecting from the cribs of the dam itself.

**Abutments and Discharge Gates.**—Abutments are structures at the ends of a dam. They may be constructed from timber, masonry, or dry stonework.

If possible, abutments should have a curved outline, and should be so placed that there is no possibility of the water overflowing them, or getting behind them during floods. If the regular discharge from a dam takes place from the main face, the gates may be arranged in connection with one of the abutments, or by means of a tunnel and culvert through the dam. In either case, some structure should be constructed above the outlet so as to prevent driftwood, brush, and other material from stopping the discharge gates. When the discharge gates are placed at one side of the dam, they are usually arranged outside of the regular abutment, between it and a special abutment, the discharge being through a series of gates into a flume, ditch, or pipe.

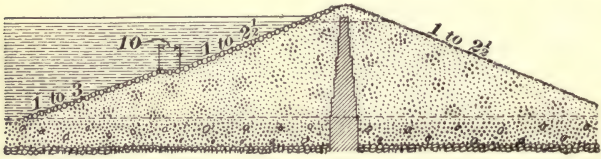
**Spillways, or Waste Ways.**—Spillways, or waste ways are openings provided in a dam for the discharge of water during floods or freshets, or for the discharge of a portion not being used at any time. The spillway may be over the crest of the dam; though, where the topography favors such a construction, the main dam may be of sufficient height to prevent water from passing its crest and the spillway arranged at another outlet over a lower dam. Waste ways, proper, are openings through the dam, and are intended for the discharge of the large quantities of water that come down during freshets or floods. In the case of timber dams, the waste ways are usually surrounded by heavy cribs, and have an area of from 40 to 50 sq. ft. each.

There are two general forms of construction employed for waste ways. One consists of a comparatively narrow opening in the dam, extending to a considerable depth (8 or 10 ft.). Water is allowed to discharge through this during flood time, but when it is desired to stop the flow, planks are placed across the up-stream face of the opening in such a manner as to close it. The opening, which is usually not over 3 or 4 ft. wide, is provided with guides on the upper face of the dam; between these the planks are slid down, the individual pieces of planking being at least 1 ft. longer than the opening that they are to cover. The other device frequently used consists in providing the waste way, at one side of the regular spillway, with a crest 2 or 3 ft. lower than the regular spillway. The crest of this waste way is composed of heavy timber, and 4 or 5 ft. above there is placed a parallel timber; the space between the two is then closed by *flash boards*, which are pieces of 2- in. or 3-in. plank, 6 or 8 in. wide, and long enough to extend from 1 to 2 ft. above the upper timber. The planks are placed against both timbers so as to close the space. Through the upper end of each plank is bored a hole through which a piece of rope is passed and a knot tied in the end of the rope; these ropes are secured by staples to the upper timber. When it becomes necessary to open the waste way, men go under with peevies, cant hooks, or pinch bars, and pry up the planks in such a way as to draw the longer end out of contact with the lower timber, when the force of the water will immediately carry the plank down the stream as far as the rope will allow. After the first plank has been loosened, the succeeding ones can be pulled up with comparative ease, and two men can open a 25-ft. or 30-ft. section of waste way in a very few minutes. The ropes keep the plank from being lost, and the opening can be closed again by passing the planks down into the water to one side of the opening and moving them into the current. Some skill is required both in opening and closing the waste ways.

**Stone Dams.**—Where cement or lime is expensive, but where suitable rubble stone can be obtained, dams are frequently constructed without the use of mortar. In such cases, the upper and lower faces of the dam should be of hammer-dressed stone, carefully bonded, and sometimes the stones in the lower face of the dam are anchored by means of bolts. The dam can be made watertight by placing a skin of planking on the upper face. In case water should ever pass over the crest of such a dam, much of it will settle through the openings in the stone into the interior of the dam, and subject the stones in the lower portion of the face to a hydrostatic pressure, provided an opening has not been made for the escape of such water. For this reason, culverts or openings should be made through the lower portion of the dam, to discharge any such water. When such dams as this are constructed, the regular spillway is not placed over the face of the dam, but at some other point, and usually over a timber dam.

**Earth Dams.**—Earth dams are used for reservoirs of moderate height. They should be at least 10 ft. wide on top, and a height of more than 60 ft. is unusual. When the material of which the dam is composed is not water-tight, as for instance, gravel, sand, etc., it is sometimes necessary to construct a puddle wall of clay in the center of the regular dam. This consists of a narrow dam of clay mixed with a certain proportion of sand. The puddle wall

should not be less than from 6 to 8 ft. thick at the top of the dam, and should be given a slight batter on each side. It is constructed during the building of the dam, and should be protected from contact with the water by a considerable thickness of earth on the upper face. The upper face of an earthen dam is frequently protected by means of plank or a pavement of stone. The lower face is frequently protected by means of sod, or sod and willow trees. Sometimes earth dams are provided with a masonry core in place of the puddle



wall, to render them water-tight. This consists of a masonry wall carried to an impervious stratum, and up through the center of the dam. The masonry core should never be less than 2 or 3 ft. thick at the top, and should be given a batter of at least 10% on each side. At the regular water level, earthen dams are liable to have a small bench or shelf formed, and on this account, during the construction, such a bench or shelf is sometimes built into the earth dam. The accompanying figure shows a dam with a masonry core, with the upper face covered with rubble and the lower face covered with grass.

## IRRIGATION QUANTITY TABLES

| Amount of Water Required to Cover 1 A. to Given Depths | | | Second-Feet Reduced to Gallons and Acre-Feet* | | | | Gallons Required to Cover a Given Number of Acres to Depth of 1 Ft. | |
|---|---|---|---|---|---|---|---|---|
| Depth | | Cubic Feet, or Second Feet, Contained in 1 A. | Gallons | Second-Feet | Gallons per Minute | Gallons per Pumping Day of 12 Hr. | Acre-Feet per Pumping Day of 12 Hr. | Acres, or Number of Acre-Feet | Gallons |
| Ft. | In. | | | | | | | | |

*One cubic foot of water per second (exact 7.48052 gal.) constant flow is known as the *second-foot*.
   The *acre-foot* is the quantity of water required to cover 1 A. to a depth of 1 ft.

**Refuse Dams.**—Refuse dams are placed across the bed of streams to hold back refuse from mines and washeries, and to prevent damage to the valleys below. They are made of stone, timber, or brush. No attempt is made to render the refuse dam water-tight, the only object being that it should retard the flow of the stream and give it a greater breadth of discharge, so that the water naturally drops and deposits the sediment that it is carrying. The sediment soon silts or fills up against the face of the dam, the area above the dam becoming a flat expanse or plain over which the water finds its way to the dam. When these dams are constructed of stone, the individual stones on the lower face and crest of the dam should be so large that the current will be unable to displace them, while the upper face and core of the dam may be composed of finer material. In case a breach should occur in the refuse dam, it will not necessarily endanger the region farther down the stream, as is the case when a break occurs in a water dam. The reason for this is that the refuse dam is not made watertight, and hence there is never much pressure against it, or a large volume of water held back that can rush suddenly down the stream should a break occur. The only result of the break would be that more or less of the gravel, sand, slate, etc., behind the dam would be washed through the breach.

**Wing Dams.**—Wing dams are used for turning streams from their courses, so as to expose all or a portion of the bed for placer mining or other purposes. They are usually of a temporary nature, and are constructed of brush and stones, light cribs filled with stones, and of large stones, or timber. Sometimes the course of a stream is turned by an obstruction made of sand bags and a wing dam constructed behind this of frames of timber, the intervening space being filled with gravel or earth; in some cases, the timber is covered with stone and the surface riprapped so that if the flow ever comes over the top of the structure it will not destroy it.

**Masonry and Concrete Dams.**—When high masonry or concrete dams are to be employed they should be designed by a competent hydraulic engineer. Masonry or concrete dams are not, as a rule, used around coal mines, owing to the fact that the length of time during which the dam is required rarely warrants such expensive construction.

# WATER-POWER

**Theoretical Efficiency of Water-Power.**—The gross power of a fall of water is the product of the weight of water discharged in a unit of time, and the total head or difference in elevation of the surface of the water, above and below the fall. The term head, used in connection with waterwheels, is the difference in height between the surface of water in the penstock and that in the tailrace, when the wheel is running.

If $Q$ = cubic feet of water discharged per minute;
$W$ = weight of 1 cu. ft. of water = 62.5 lb.;
$H$ = total head, in feet;
$WQH$ = gross power, in foot-pounds per minute;
$\dfrac{WQH}{33,000}$ = horsepower.

Substituting the value for $W$, gives

$$\frac{QH \times 62.5}{33,000} = .00189QH, \text{ as horsepower of a fall.}$$

The total power can never be utilized by any form of motor, because there is a loss of head, both at the entrance to, and exit from, the wheel, and there are also, losses of energy due to friction of the water in passing through the wheel. The ratio of the power developed by the wheel to the gross power of the fall, is the efficiency of the wheel. A head of water can be made use of in any one of the following ways:

1. By its weight, as in the water balance, or overshot wheel.
2. By its pressure, as in the hydraulic engine, hydraulic presses, cranes, etc., or in a turbine water wheel.
3. By its impulse, as in the undershot and impulse wheels, such as Peltons, etc.
4. By a combination of these.

**Horsepower of a Running Stream.**—The gross horsepower is

$$\text{H. P.} = \frac{QH \times 62.5}{33,000} = .00189QH$$

in which $Q$ = quantity actually impinging on float or bucket, in cubic feet per minute;

$H$ = theoretical head added to velocity of stream.

or
$$H = \frac{v^2}{2g} = \frac{v^2}{64.4},$$

in which $v$ = velocity, in feet per second.

For example, if the floats of an undershot waterwheel are 2 ft.×10 ft., and the stream has a velocity of 3 ft, per sec., i. e., $v=3$, $H = 9 \div 64.4 = .139$, and $Q = 2 \times 10 \times 3 \times 60 = 3,600$ cu. ft. per min.

From this, H. P. $= 3,600 \times .139 \times .00189 = .945$ H. P., or a gross horsepower for practically .05 sq. ft. of wheel surface; but, under ordinary circumstances, it is impossible to attain more than 40% of this, or practically .02 H. P. per sq. ft. of surface, which requires 50 sq. ft. of float surface to each horsepower furnished.

**Current Motors.**—A current motor fully utilizes the energy of a stream only when it is so arranged that it can take all the velocity out of the water; that is, when the water leaves the floats or vanes with no velocity. In practice, it is impossible to obtain even a close approximation to these results, and hence only a small fraction of the energy of a running stream can be utilized by the current motor.

Current motors are frequently used to obtain small amounts of power from a large stream, as, for instance, for pumping a limited amount of water for irrigation. For this work, an ordinary undershot wheel having radial paddles is usually employed. At one end of the wheel a series of small buckets is placed, and so arranged that each bucket will dip up water at the bottom of the wheel and discharge it into the launder, near the top of the wheel. The shape of the buckets should be such that only the amount of water that the bucket is capable of carrying to the launder will be dipped up, for, if the bucket is constantly slopping or pouring water as it ascends, a large amount of useless work is performed in raising this extra water and then pouring it out again, as only the portion that reaches the launder can be of any service. Current motors are not practicable for furnishing large amounts of power.

**Utilizing Power of Waterfall.**—The power of a waterfall may be utilized by a number of different styles of motors, but each has certain advantages.

When the head is low (not over 5 or 6 ft.), *breast or undershot wheels* are frequently employed. If these are properly proportioned, it is possible to realize from 25% to 50% of the theoretical power of the fall, but the wheels are large and cumbersome compared with the duty they perform, and are not often installed at present, especially near manufacturing centers.

For falls up to 40 or 50 ft., *overshot wheels* are very commonly employed, and they have been used for even greater heads than this. The overshot wheel derives its power both from the impulse of the water entering the buckets, and from the weight of the water as it descends on one side of the wheel in the buckets; the latter factor is by far the more important of the two. When properly proportioned, overshot wheels may realize from 70% to 90% of the power of the waterfall, but they are large and cumbersome compared with the power that they give, and are not often installed except in isolated regions, where they are made from timber by local mechanics.

For heads varying from 50 ft. up, *impulse wheels* are very largely used. These are also sometimes called *hurdy gurdies*, and are usually of the Pelton type, consisting of a wheel provided with buckets, so arranged about its periphery that they receive an impinging jet of water and turn it back upon itself, discharging it with practically no velocity, and converting practically all the energy into useful work. The efficiency of these wheels varies from 85% to 90% under favorable circumstances. This style of wheel is especially adapted for very high heads and comparatively small amounts of water. There are a number of instances where wheels are operating under a head of as much as 2,000 ft. This style of impulse wheel is an American development; in Europe, a style of impulse turbine has been used to some extent, but has not found very much favor in the United States.

*Turbines*, or *reaction wheels*, are very largely employed, especially for moderate heads. When properly designed to fit the working conditions, they can be used for heads varying from 4 to 5 ft. up to considerably over 100 ft., and when properly placed are capable of utilizing the entire head, a factor that gives them a decided advantage over any other style of waterwheel. Turbines are capable of returning 85% to 90% of the theoretical energy as useful power, and are largely used, especially where a considerable volume of water at a low head, or a smaller volume at a moderate head, can be obtained.

## PUMP MACHINERY

### CLASSIFICATION OF PUMPS

*Pumps* are employed for unwatering mines, handling water at placer mines, irrigation, water-supply systems, boiler feeds, etc. For unwatering mines, two general systems of pumping are employed: (1) The pump is placed in the mine and is operated by a motor on the surface, the power being transmitted through a line of moving rods. (2) Both the motor and pump are placed in the mine, the motor being an engine driven by steam, compressed air, hydraulic motor, or an electric motor.

**Cornish Pumps.**—Any method of operating pumps by rods is commonly called a *Cornish system*. Formerly, the motor in the Cornish system consisted of a steam engine placed over the shaft head, which operated the pump by a direct line of rods. With this arrangement, there is great danger of accident to the engine from the settling of the ground around the shaft, or from fire in the shaft; also, the position of the motor renders access to the shaft difficult. To overcome these objections, the engine is frequently placed at one side of the shaft, and the rods operated by a bob; this has become the common practice, and is generally called the *Cornish rig*. The engine employed in the most modern plants is generally of the Corliss type, and is provided with a governor to guard against the possibility of the engine running away, in case the rods should break.

This system requires no steam line down the shaft, and is independent of the depth of water in the mine, so that the pump is not stopped by the drowning of a mine, but the moving rods are a great inconvenience in the shaft, and they absorb a great amount of power by friction.

**Simple and Duplex Pumps.**—In the simple pumps a steam cylinder is connected directly to a water cylinder, and the steam valves are operated by tappets. Such a pump is more or less dependent on inertia at certain points of the stroke to insure the motion of the valves, hence will not start from any place, but is liable to become stalled at times.

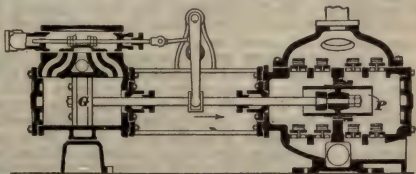
In the duplex pump, two steam cylinders and two water cylinders are arranged side by side, and the valves so placed that when one piston is at mid-stroke it throws the steam valve for the other cylinder, etc. With this arrangement, the pump will start from any point, and can never be stalled for lack of steam, due to the position of the valves. Ordinarily, duplex pumps are to be preferred for mine work.

The *packing* for the water piston of a pump may be either inside or outside. Any form of packing that is inside the cylinder, either upon a moving piston or surrounding the ram, and so situated that any wear will allow communication between the opposite ends of the cylinder, is called *inside* packing. It may consist simply of piston rings about the piston, as in the case of an ordinary steam-engine piston *G*, Fig. 1, or stationary rings may be employed about the outside of a moving ram, or long piston *P*. In either case,

FIG. 1

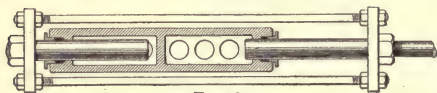
the cylinder heads have to be removed before the condition of the packing can be inspected, and any leak does not make itself visible.

When outside packing is employed, separate rams are used in opposite ends of the cylinder, there being no internal communication between the chambers in which the rams work. The rams are packed by ordinary outside stuffingboxes and glands. The arrangement consists practically of two single-acting pumps arranged to work alternately, so that one is forcing water while the other is drawing water. Fig. 2 shows a horizontal section of a cylinder so arranged, together with the yoke rods that operate the ram at the farther end of the cylinder.

As a rule, inside-packed pumps should be avoided in mines, because acid or gritty waters are liable to cut the packing, and make the pumps leak in a


very short time. For dipping work in single stopes or entries, small single or duplex outside-packed pumps may be employed. It is generally best to operate such pumps by compressed air, for the exhaust will then be beneficial

FIG. 2

to the mine air. If steam is employed, it is frequently necessary to introduce a trap and remove entrailed water from the steam before it enters the pump, and to dispose of the exhaust by piping it out or condensing it. Such isolated steam pumps are about the most wasteful form of steam-driven motor in existence.


For sinking, center-packed single or duplex pumps are usually employed, the duplex style being the better. For station work, where much water is to be handled, large compound, or triple-expansion, condensing, duplex pumping engines are employed. They may, or may not, be provided with cranks and a flywheel. Engineers differ greatly upon this point, and, as a rule, for very high lifts and great pressures, the flywheel is employed.

The main points in consideration are the first cost of the pump, and the amount that will be saved by using the more expensive engine. The large flywheel pumping engines are several times as expensive as the direct-acting steam pumps, and the question is as to whether their greater efficiency will more than counterbalance the increased outlay. Most engineers favor flywheel pumps for handling large volumes of water where the work is approximately constant, and direct-acting pumps, without flywheels or cranks, for handling small amounts of water, or for very irregular service, owing to the fact that if the flywheel pump is driven below its normal speed it does not govern properly, nor work economically. Until recently, water was removed from mines in lifts of about 300 to 350 ft., pumps being placed at stations along the shaft.

While a series of station pumps are still employed in some cases, they are generally intended to take care of water coming into the shaft, or workings at or near their level, and are not employed for handling water in successive stages or lifts. For handling the bulk of the water from the bottom of the shaft, large pumping engines are employed that frequently force the water to the surface from depths of over 1,000 ft. These high-duty pumping plants, when near the shaft and operated by steam with a condenser, frequently show a very high efficiency. When air is employed to operate such a plant, a much higher efficiency can be obtained if the compressed air is heated before it is used in the high-pressure cylinder and during its passage from the high-pressure to the low-pressure cylinder. This has been very successfully accomplished by means of a steam reheater, the small amount of steam necessary being conveyed to the station in the small pipe, and entirely condensed in the reheater, from which it is trapped as water.

The duty of steam pumps is approximately as follows: For small-sized steam pumps, the steam consumption is from 130 to 200 lb. per H. P. per hr., when operating in the workings of a mine at some distance from the boiler. For larger sizes of simple steam pumps, the consumption runs from 80 to 130 lb. per H. P. per hr. Compound-condensing pumps, such as are commonly used as station pumps, consume from 40 to 70 lb. per H. P. per hr. Triple-expansion, condensing, high-class pumping engines consume from 24 to 26 lb. per H. P. per hr. The Cornish pump consumes varied amounts of steam in proportion to the water delivered, depending largely on the friction of the gearing, bobs, rods, etc., but its efficiency is usually considerably below the best class of pumping engines.

**Speed of Water Through Valves, Pipes, and Pump Passages.**—The speed of water through the valves and passages of a pump should not exceed 250 ft. per min., and care should be taken to see that the passages are not too abruptly deflected. The flow of water through the discharge pipe should not exceed 500 ft. per min., and for single-cylindered pumps it is usually figured at between 250 and 400 ft. per min. In the case of very large pumps, greater velocities may be allowed. The suction pipe for the pump should be larger than the discharge pipe. Ordinarily the suction pipe for a pump should not exceed 250 ft. in length, and should not contain more than two elbows. The following formula gives the diameter of the suction and discharge pipes of a pump:

$G$ = United States gallons per minute;
$d'$ = diameter of suction pipe, in inches;

$d''$ = diameter of discharge pipe, in inches;
$v'$ = velocity of water, in feet per minute, in suction pipe = from $.50v''$ to $.75v''$
$v''$ = velocity of water, in feet per minute, in discharge pipe.

$$d' = 4.95 \sqrt{\frac{G}{v'}} \qquad\qquad d'' = 4.95 \sqrt{\frac{G}{v''}}$$

## RATIO OF STEAM AND WATER CYLINDERS IN A DIRECT-ACTING PUMP

Let $A$ = area of steam cylinder;
$D$ = diameter of steam cylinder;
$P$ = steam pressure, in pounds per square inch;
$H$ = head of water = $2.309p$;
$a$ = area of pump cylinder;
$d$ = diameter of pump cylinder;
$p$ = pressure per square inch, corresponding to head $H = .433H$;
$E$ = efficiency of pump = $\dfrac{\text{work done in pump cylinder}}{\text{work done in steam cylinder}}$;

$$A = \frac{ap}{EP} \qquad d = D\sqrt{\frac{EP}{p}} \qquad \frac{A}{a} = \frac{p}{EP} = \frac{.433H}{EP}$$

$$a = \frac{EAP}{p}; \qquad P = \frac{ap}{EA}; $$

$$D = d\sqrt{\frac{p}{EP}} \qquad p = \frac{EAP}{a}; \qquad H = 2.309EP \times \frac{A}{a}.$$

If $E = 75\%$, then $H = 1.732P \times \dfrac{A}{a}$.

$E$ is commonly taken at from .7 to .8 for ordinary direct-acting pumps. For the highest class of pumping engines it may amount to .9. The steam pressure $P$ is the mean effective pressure, according to the indicator diagram; the pressure $p$ is the mean total pressure acting on the pump plunger or piston, including the suction, as would be shown by the indicator diagram of the water cylinder. The pressure on the pump cylinder is frequently much greater than that due to the height of the lift, on account of the friction in the valves and passages, which increases rapidly with the velocity of the flow.

**Piston Speed of Pumps.**—For small pumps, it is customary to assume a speed of 100 ft. per min., but, in the case of very small short-stroke pumps, this is too high, owing to the fact that the rapid reverses make the flow through the valves and change in the direction of the current too frequent. When the stroke of the pump is somewhat longer (18 in. or more), higher speeds can be employed, and in the case of large pumping engines having long strokes, speeds of as much as 200 to 250 ft. per min. are successfully used without jar or hammer.

### STROKES FOR PISTON SPEED OF 100 FT. PER MIN.

| Length of Stroke Inches | Number of Strokes | Length of Stroke Inches | Number of Strokes | Length of Stroke Inches | Number of Strokes |
|---|---|---|---|---|---|
| 4 | 300 | 12 | 100 | 24 | 50 |
| 5 | 240 | 14 | 86 | 26 | 46 |
| 6 | 200 | 16 | 75 | 28 | 43 |
| 7 | 172 | 18 | 67 | 30 | 40 |
| 8 | 150 | 20 | 60 | 36 | 33 |
| 10 | 120 | 22 | 55 | 40 | 30 |

**Boiler Feed-Pumps.**—In practice, it has been shown that a piston speed greater than 100 ft. per min. results in excessive wear and tear on a boiler feed-pump, especially when the water is warm. This is because vapor forms in the cylinders, and results in a water hammer. In determining the proper size of a pump for feeding a steam boiler, not only the steam employed in running the engine, but that necessary for the pumps, heating system, etc. must be taken into consideration.

## THEORETICAL CAPACITY OF PUMPS AND HORSEPOWER REQUIRED TO RAISE WATER

Let $Q$ = cubic feet of water per minute;
$G$ = United States gallons per minute;
$G'$ = United States gallons per hour;
$d$ = diameter of cylinder, in inches;
$l$ = stroke of piston, in inches;
$N$ = number of single strokes per minute;
$v$ = speed of piston, in feet per minute;

### RATIOS OF AREAS TO DIAMETERS

| Diameter of Water Cylinders Inches | Diameter of Steam Cylinder, in Inches | | | | | |

| 12 | | .25 | .44 | .69 | 1.00 | 1.36 |
| 13 | | | .37 | .59 | .85 | 1.16 |
| 14 | | | .33 | .51 | .73 | 1.00 |
| 15 | | | .28 | .44 | .64 | .87 |
| 16 | | | .25 | .39 | .56 | .76 |
| 17 | | | | .34 | .49 | .67 |
| 18 | | | | .30 | .44 | .60 |

$W$ = weight moved, in pounds per minute;
$P$ = pressure, in pounds per square foot = $62.5H$;
$p$ = pressure, in pounds per square inch = $.433H$;
$H$ = height of lift, in feet;
H. P. = horsepower.

Then,

$$Q = \frac{\pi}{4} \times \frac{d^2}{144} \times \frac{Nl}{12} = .0004545 N d^2 l$$

$$G = \frac{\pi}{4} \times \frac{N d^2 l}{231} = .0034 d^2 l \qquad\qquad G' = .204 N d^2 l$$

## OF STEAM AND WATER CYLINDERS

| Diameter of Steam Cylinders, in Inches | | | | | | | |

| .79 | 1.00 | 1.23 | 1.49 | 1.77 | 2.08 | 2.41 | 2.77 |

The diameter of piston required for a given capacity per minute will be

$$d = 46.9 \sqrt{\frac{Q}{Nl}} = 17.15 \sqrt{\frac{G}{Nl}}, \text{ or } d = 13.54 \sqrt{\frac{Q}{v}} = 4.95 \sqrt{\frac{G}{v}}$$

The actual capacity of a pump will vary from 60% to 95% of the theoretical capacity, depending on the tightness of the piston, valves, suction pipe, etc.

$$\text{H. P.} = \frac{QP}{33,000} = \frac{QH \times 144 \times .433}{33,000} = \frac{QH}{529.2} = \frac{Gp}{1,714.5}$$

The actual horsepower required will be considerably greater than the theoretical, on account of the friction in the pump; hence, at least 20% should be added to the power for friction and usually about 50% more is added to cover leaks, etc., so that the actual horsepower required by the pump is about 70% more than the theoretical.

EXAMPLE 1.—What size of pump will throw 30 gal. of water per min. up 125 ft., from the bottom of a pit or prospect shaft to the station pump at the main shaft?

SOLUTION.—An allowance of probably 25% should be made with a small pump of this character, to overcome slippage or leaking through the valves, past the piston, etc., and hence the total amount of water to be handled is 40 gal. per min. The formula for the diameter of piston is $d = 4.95 \sqrt{\frac{G}{v}}$; therefore, assuming that $v = 100$ ft. per min., $d = 4.95 \sqrt{.4} = 4.95 \times .63 = 3.12$. In practice, a $3\frac{1}{2}$-in. pump will probably be employed.

EXAMPLE 2.—Find the approximate horsepower necessary to lift 30 gal. per min. in Example 1.

SOLUTION.—

$$\text{H. P.} = \frac{Gp}{1,714.5} = \frac{30 \times .433 \times 125}{1,714.5} = .95, \text{ or practically 1 H. P.}$$

In order to cover leakage through valves, friction, etc., an addition of at least 75% should be made to a very small pump like this, and so $1\frac{3}{4}$ H. P. would be counted on.

The table on page 339 gives theoretical horsepowers only. Approximately the actual horsepower for a 100-ft. lift may be found by multiplying the tabular figures by 1.7; for a 200-ft. lift, by 1.45; and for a 300-ft. lift, by 1.3, for triplex pumps.

**Depth of Suction.**—Theoretically, a perfect pump will raise water to a height of nearly 34 ft. at the sea level; but, owing to the fact that a perfect vacuum can never be attained with the pump, that the water always contains more or less air, and that more or less watery vapor will form below the piston, it is never possible to reach this theoretical limit, and, in practice, it is not possible to draw water much, if any, over 30 ft. at the sea level, even when the water is cold. Warm water cannot be lifted as high as cold water because a larger amount of watery vapor forms. With boiler feed-pumps handling hot water, for pumps should flow to the pumps by gravity.

For pumps and connections in the best possible condition, it is generally figured that the suction lift will be three-fourths of that theoretically possible. However, pumps are very commonly out of order to a certain degree so that the lifts given in the following table agree very well with actual practice.

## SUCTION LIFT OF PUMPS AT DIFFERENT ALTITUDES

| Altitude Above Sea Level | | Atmospheric Pressure at Altitude Pounds per Square Inch | Theoretical Lift Feet | Practical Lift Feet |
|---|---|---|---|---|
| Miles | Feet | | | |
| $\frac{1}{4}$ | 1,320 | 14.70 | 33.95 | 22 |
| $\frac{1}{4}$ | 2,640 | 14.02 | 32.38 | 21 |

**Amount of Water Raised by a Single-Acting Lift Pump.**—In the case of all pumps having a piston or ram, the amount of water lifted is usually considerably less than the piston displacement, owing to the leakage through the valves, etc., but with single-acting lift pumps, having bucket plungers with a clack valve in the plunger, the amount lifted may actually exceed the plunger displacement; that is, the volume of water may actually be greater than the length of the stroke multiplied by the number of strokes, for, during the up-stroke, the water both above and below the piston is set in motion, and during the down-stroke, the inertia of the water actually carries more water through the valve than would pass through it on account of the space passed through. This increases as the speed or number of strokes increases.

**Capacity of Pumps.**—In the accompanying table are given the capacities of pumps; these values are for single strokes; to find the capacity for one revolution the capacity for a stroke must be multiplied by **2**.

## CAPACITY OF PUMPS

| Diameter of Piston or Plunger, Inches | Length of Piston or Plunger Stroke, in Inches | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | 2 | 3 | 4 | 5 | 6 | 7 | 12 | 13 |

**Pump Valves.**—As a rule, a large number of small valves having a comparatively small opening are preferable to a small number of large valves with a greater opening, and most modern pumps are built on these lines. A small valve represents a proportionately larger surface of discharge with the same lift than the large valve, hence whatever the total area of the valve-seat opening, its full contents can be discharged with less lift through numerous small valves than through one large valve. Cornish pumps generally have one large metal valve.

## POWER PUMPS

In a power pump the reciprocating motion is transmitted to the water plunger or piston by means of a crank driven by belting or gearing, instead of in a straight line directly from the steam or air piston. Power pumps are not

generally used for pumping against heavy pressures. They may be single, duplex, or triplex, single-acting or double-acting, and either of piston or plunger types, although double-acting and triple-acting plunger pumps are the most common. The triplex pump consists of three single-acting plunger pumps driven by cranks 120° apart on a single shaft. A tight and a loose pulley provide the means for starting and stopping the pump without disturbing the engine on the main shaft. The pulley shaft is geared to the crank-shaft by a pinion and spur wheel. By setting the cranks 120° apart, the strokes follow and overlap one another giving a uniform flow of water and a uniform expenditure of power. In the case of duplex single-acting pumps, the cranks are placed 180° apart and the discharge is the same as from one double-acting pump of the same diameter of plunger and length of stroke. Duplex, double-acting power pumps with their cranks set 90° apart give a steady discharge, for when one plunger is at the end of its stroke and at rest, the other plunger is moving and discharging water at its maximum rate. The crank-shaft of these pumps is sometimes supplied with gears at each end to equalize the strain, particularly when heavy pressures are to be overcome.

**Electrically Driven Power Pumps.**—Where water is to be delivered from isolated workings to the sumps for the large station pumps, electrically driven power pumps are far more efficient than steam pumps. In some cases, it is probably best to equip the entire mine with electric pumps, both in the isolated workings and at the stations, because they can be driven by a high-class compound-condensing engine on the surface, directly connected to a generator, and furnishing electricity through conductors to the various pumps.

The total efficiency of a series of small electric pumps that aggregate a sufficient amount of power to enable this arrangement to be used, is very much higher than the total efficiency of a number of small isolated steam or compressed-air pumps introduced into the workings. With compound-condensing engines upon the surface, operating electric pumps underground, the steam consumption per pump horsepower per hour, for the smaller sizes, would only be about 40 lb. per H. P. per hr.; for medium-sized electric pumps, about 30 lb. per hr., and larger sizes from 20 to 30 lb. per H. P. per hr. These figures show that for pumping from isolated portions of the mine the electric pump is much more efficient than the steam pump, as the current can be frequently obtained from the lines operating the underground haulage system, furnishing light, etc.

An efficiency of at least 50% should be obtained in any well-designed, well-built pump, so that a close approximation to the actual current consumption can be obtained by doubling the theoretical consumption given in the accompanying table.

## THEORETICAL CONSUMPTION OF ELECTRIC CURRENT FOR PUMPING WATER PER 1,000 GAL.

| Total Elevation Feet | Equivalent Pressure per Square Inch | Kilowatts per 1,000 Gal. | Total Elevation Feet | Equivalent Pressure per Square Inch | Kilowatts per 1,000 Gal. |
|---|---|---|---|---|---|
| 10 | 4.33 | .0312 | 160 | 69.29 | .500 |
| 20 | 8.66 | .0624 | 170 | 73.63 | .531 |
| 30 | 12.99 | .0937 | 180 | 77.96 | .562 |
| 40 | 17.32 | .124 | 190 | 82.29 | .593 |
| 50 | 21.65 | .156 | 200 | 86.62 | .624 |
| 60 | 25.99 | .187 | 210 | 91.14 | .655 |
| 70 | 30.32 | .218 | 220 | 95.48 | .686 |
| 80 | 34.65 | .249 | 230 | 99.82 | .717 |
| 90 | 38.95 | .281 | 240 | 104.16 | .748 |
| 100 | 43.31 | .312 | 250 | 108.50 | .779 |
| 110 | 47.64 | .343 | 260 | 112.84 | .813 |
| 120 | 51.97 | .374 | 270 | 116.91 | .841 |
| 130 | 56.30 | .406 | 280 | 121.24 | .875 |
| 140 | 60.63 | .437 | 290 | 125.57 | .903 |
| 150 | 64.96 | .468 | 300 | 129.90 | .934 |

**Precautions Necessary With Electrically Driven Mine Pumps.**—Where electricity is used in mining, the prevailing tendency is to lay the blame for troubles of various kinds to its use, because electricity is the least understood and most mysterious force employed. It is especially important, therefore, that every precaution be taken to minimize the possibility of accident from electric causes, either by shock or by fire. While bare wires are necessarily employed as trolley wires, all wires used as feeders, on the headings, and wires leading to the pump should be well insulated, as even a slight shock received by the attendant working at or near the pump, or trackmen, or timbermen working on the entries, may prove fatal should the man receiving the shock fall against the exposed wire. Whenever possible, a dry, wooden platform should be provided about the pump; or, if this is considered objectionable on account of the fire risk, a good, dry, cement floor should be laid in the pump room. A small stool with insulator pins and glasses for legs forms a safeguard and should be used whenever it is necessary to adjust or change brushes or work on the commutator while running.

It is hardly surprising that a fire should originate in a mine when a small electric pump is placed on a wooden floor in a frame pump house and the attendant has a seat or bunk with straw mattress, where he reclines and smokes; or when oil and waste are thrown about and the fuse boxes and rheostat are fastened to a board placed against an inflammable partition, while a strong draft passing through the place, and no available means at hand of extinguishing a fire adds to the danger.

The following precautions are advised in placing an electric pump: Place the pump, if possible, in a special room excavated for the purpose. Where a break-through or passage between two rooms must be used, it should be closed with brick or stone and not with wooden brattice. Make the place fireproof; allow no wooden boxes or furnishings of inflammable material; enforce strict regulations in regard to oil and waste used about the pump; have a dry, cement floor and keep it clean. Matches must not be left in or around the pump house, or any illuminating oil kept therein, and lubricating oils should be carried to the pump house only in small quantities and in closed cans. Cotton waste when saturated with oil is liable to spontaneous combustion, and should be thrown into a tight can and taken out of the mine each day. The discharge pipe of the pump should be tapped with 1-in. connections, and a length of hose with a nozzle kept in the pump house ready for use in case of fire.

The pump house should be well lighted by incandescent lamps. Where lamps are used in series, at least two circuits should be run, since one burn-out will extinguish an entire series. The transmission wire for the pump should be strung on glass or porcelain insulators and care taken to prevent contact with the pump frame or the mine timbers. The line should be taken as directly as possible to the switch and fuses, and should be protected against a series ground or a short circuit.

The following table gives the gallons per minute delivered from various sized pumps operating at different piston speeds.

**Centrifugal Pumps.**—In mining practice, centrifugal pumps commonly driven by an electric motor placed on the same shaft, have been used for many years in raising water from local dips and swamps into the main sump. The absence of valves makes them well adapted to pumping dirty or gritty water and the fact that the moving parts have a rotatory instead of a reciprocating motion makes them especially suitable where electric power is available. Their small size, and consequent portability, is a commending feature for underground work. Where the water is strongly acid these pumps probably wear out sooner than ordinary reciprocating pumps unless made of special acid-resisting metal.

The original form of single-stage centrifugal pump was designed for handling large volumes of water under small heads, say, from 60 to 100 ft. In modern installations, heads of 500 ft., 750 ft., and even more, are overcome by the use of multistage pumps, so that this type is now frequently used in pumping from the main sump to the surface in one operation.

The pump consists of a series of revolving, turbine-like wheels or impellers, set side by side on the same shaft. The water thrown off by the first wheel is taken up by the second and by it passed on to the third, and similarly, according to the number of stages. If there is but one revolving part or impeller, which throws the water into the discharge pipe, the pump is *single-stage*; if there are two revolving parts, the second discharging the water forced into it by the first, it is a *two-stage pump*, and similarly for each additional revolving

## DISCHARGE OF PUMPS AT VARIOUS PISTON SPEEDS

| Diameter of Cylinder Inches | Area Square Inches | Contents for 1 Ft. Length | | Gallons per Minute Delivered at Indicated Piston Speeds* | | | | | | | | | | | |

*1 gal. = 231 cu. in. = .13368 cu. ft.; 1 cu. ft. = 1728 cu. in.; 1 gal. of water at 39.2° = 8.33888 lb.; 1 cu. ft. of water = 7.48052 gal., and weighs 62.423 lb.

part. These pumps are designated by the size of their outlet as, for instance, a 2-in. or 4-in. pump, meaning with a 2-in. or 4-in. discharge pipe.

The height of lift depends on the quantity of water to be discharged and the circumferential velocity of the revolving disk and is proportional to the area of the discharge orifices at the circumference of the disk. The circumferential velocity depends on the diameter of the disks as well as on the number of revolutions per minute. As the number of revolutions per minute is commonly limited by those of the electric driving motor, the diameter of the disks, that is, the size of the wheel or pump, is varied to suit the head against which the machine is working. For a given lift, the total efficiency of centrifugal pumps increases with the size of the pump, being about .45 to .50 for the smallest sizes of single stage pumps, and .70 to .75 for the largest, the multistage pumps giving better results.

One of the most important points to investigate when selecting a centrifugal pump is the total head against which it will have to work, as this head determines the speed at which the pump can most economically run and the speed determines the size necessary to throw a given volume of water. The horsepower may be determined by the same formula used for reciprocating pumps,

$$BHP = (GPM \times \text{head in feet}) \div (3,960 \times \text{efficiency of pump}),$$

in which, $BHP$ = brake horsepower;

$GPM$ = number of gallons to be delivered per minute.

In this formula, if the efficiency is made equal to unity, the horsepower determined will be the net horsepower theoretically required to raise the given number of gallons the given height. As stated, the efficiency varies widely, and may be taken at .50 for small wheels operating under low heads and .75 for large multistage wheels operating under high heads. However, the determination of the proper size of pump had better be left to the manufacturer who, on receipt of the proper data, will supply the right kind and size of pump and will guarantee its efficiency. The data required are the quantity of water to be pumped per minute and its kind (clean, acid, muddy, gritty, etc., size of grains of impurity, etc.), the suction lift, or distance from the water level in the sump to the center line of the pump, the discharge lift, or difference in elevation between the center line of the pump and the point of discharge, together with a sketch showing a plan of the discharge line with its length and size and the number, location, and radius of the various bends. The pressure, in pounds per square inch, of steam or compressed air, or voltage of electric current should be given, all estimates being made for the power available at the point of its application.

When bolting the pump to the foundation, care must be taken not to spring the bedplate. Every joint in the suction pipe should be air-tight. The pump should be installed to run in the direction indicated by the arrow, wording, or other instruction stamped or cast on the casing. The stuffingboxes should be properly packed and the water-seal ring should be in the proper position. The bearings should be cleaned and filled with a good grade of engine oil. Long sweep elbows only, and as few of them as possible, should be used in the suction and discharge piping. It is also advisable to use large pipe lines, as this reduces the power necessary to drive the pump and will save money in the long run. To prevent freezing in cold weather, the pump should always be drained when not in use by unscrewing the plug in the bottom of the pump casing.

All centrifugal pumps that do not operate with pressure on the suction side (that is, all pumps drawing water from a sump that is below the level of the center of the pump) must have the casing and suction pipe filled with water before starting. This may be accomplished in various ways. Where steam or compressed air is the power an ejector is used, but this method of priming is not available in mining practice where electricity is used. If a hand primer is used, the air cock on the top of the pump is opened and the primer, which is a small hand pump, is worked until water flows through this cock. Then the pump is started.

If there is a foot-valve on the bottom of the suction pipe, the pump can be primed by running water into it from an overhead tank, or any other source of supply, as the valve will hold the water in the pump. In the event of the column pipe being full of water, as is commonly the case when the pump has been shut down temporarily (as during the night shift), a by-pass may be arranged by which the water in the column pipe may be drawn off in sufficient quantity to prime the pump. After priming, the pump can be started and, when full speed has been attained, the discharge valve opened.

## PUMPS FOR SPECIAL PURPOSES

**Sinking Pumps.**—Sinking pumps may be either single or duplex in their action, and may be inside or outside packed. Outside-packed single-acting pumps are in many ways preferable, owing to the fact that they are less liable to get out of order. One requisite of any sinking pump is that it should have as few exposed parts as possible, and that these parts should be so placed that they will be protected to as great an extent from injury by blasting as possible. Sinking pumps are usually provided with a telescopic section in the suction pipe, and sometimes also in the discharge pipe, so that they can be moved down several feet without having to break the joints of the piping.

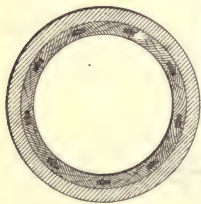
**Pumps for Acid Waters.**—Where mine waters are acid in their nature, bronze, bronze-lined, or lead lined pumps are usually employed, and in some cases even wooden pumps have been used, as, for instance, in the Swedish copper mines, though this practice is disappearing in favor of the use of bronze or copper linings. The pipes for such pumps should be of bronze or copper tubing, or should be lined with some substance that will not be affected by the acid of the water. Sometimes wooden linings are employed, placed as shown in Figs. 1 and 2, Fig. 1 being a section of the pipe with the lining complete, and Fig. 2 a cross-section of one of the individual boards used in the lining. These are usually made of pine about ⅜ in. thick, and are grooved on each end as shown.


FIG. 1      FIG. 2

They are sprung in so as to complete a circle on the inside of the pipe, and then long, thin, wooden keys driven into the grooves. When the water is allowed to go into the pipes, the linings swell and make all joints perfectly tight. Elbows and other crooked sections are lined with sheet lead beaten in with a mallet. Concrete-lined pumps have been recently introduced in mines where there is acid water.

## PUMP FOUNDATIONS

The *foundation* for pumping machinery depends entirely on the type of pump. Direct-acting duplex pumps probably require the least foundation, for the piston and plunger moving in opposite directions almost balance the machine in line with the plunger motion and the strains due to reversing are contained almost wholly within the machine itself. Small duplex-pump foundations are made of a solid mass of brick or concrete, while large pumps are often set on separate piers, one for the water end and one for the steam end. The foundations must go down to sufficiently hard material to bear the weight of the pump; or, if the substratum consists of loose sand or gravel, the foundation must be spread so that the pressure does not exceed 1 T. per sq. ft. Single pumps require a somewhat heavier foundation than duplex pumps, owing to the greater shocks to which they are subjected.

Foundations should be built of hard brick laid in cement mortar, or of concrete; or, in the case of large pumps, stone may be used. The pump should be secured to foundation bolts anchored to plates underneath the masonry. If solid rock exists at the place where the pump is to be located, the surface of the rock is leveled to suit the bedplate or footings of the pump; holes for the foundation bolts are then drilled to a sufficient depth, and the bolts, which should have a good length and a roughened shank, are placed in the holes and fastened by pouring molten lead around them.

*Pump houses,* or *pump stations* as they are often called, are generally placed near the foot of a shaft or slope in a room excavated for the purpose in the solid rock or coal. If the roof needs support, timbers or steel supports may be used.

## PUMP MANAGEMENT

All pumps, when new, should be run slowly until the parts have become thoroughly adjusted to their bearings, when the speed may be increased. Because a new pump works stiffly is no cause for alarm, for, while a machinist can properly construct the parts, he cannot always forsee the strains caused by the action of the pump, when the parts are assembled and which require certain adjustments to be made after the pump is at work. By running the pump slowly with the parts properly lubricated and making such adjustments as may be necessary, stiffness will gradually disappear and the highest efficiency

of the pump will be attained, provided other matters on which the pump's action depend have received proper attention.

The causes that affect a pump, impair its efficiency, and prevent it from performing its full duty are: wear; the improper adjustment of valves, valve stems, and levers; the improper packing of plungers and stuffingboxes; drawing up the stuffingbox glands too tightly; lost motion due to permitting the working parts to wear and not adjusting them to the new conditions; accumulations of foreign matter under the valves or in the strainer; broken valves and valve springs; leakage in valves; taking air in the suction pipe; clogged or broken discharge pipes; and the use of poor gaskets.

At many mines, the pumps are capable of a larger capacity than is obtained by the low speed at which they are run, but it is important that such pumps be run continuously, as any serious interruption in pumping might cause trouble elsewhere. It is customary, therefore, to keep on hand a supply of duplicate valves, moving parts, and packing, in order that when it becomes necessary to make repairs they may be made without great loss of time.

A common cause of pumps refusing to work properly is due to their taking air below the suction valves. Small leaks will cause the piston to jump, owing to the water not entering through the suction valves soon enough to fill the entire chamber. This trouble may be remedied by seeing that all joints in the suction pipe and between the pipe and the pump are air-tight. Leaks may sometimes be detected by the hearing or by the flame from a candle being drawn toward the hole. If the leaks are small and not at the pipe joints, a coat of asphalt paint may stop them; if large, they should be drilled larger, the hole threaded, and a screw plug inserted. If the leak is at the joint between two pipes, the pipes should be uncoupled and screwed together again, using graphite pipe grease for a lubricant; or, if the joint is a flanged one, a new gasket should be placed between the flanges, and the pipes lined up before the bolts are tightened.

Sometimes, a pump fails to catch the water when started owing to leakage of the valves in the suction chamber. The trouble may be caused by the valve and valve seat being corroded; by chips or gravel getting under the valves and preventing them from seating properly; or by the valves and seats becoming worn so that leakage cannot be prevented without changing the parts.

Many pumps that will not raise water in the suction pipe when empty, owing to the pump having been idle for some time, will continue to draw water after once being started. In such cases, it is necessary to *prime the pump*, by which is meant filling the suction pipe and part of the suction chamber, if there is one, and in some cases, also, the pump barrel, with water, so that the pump may start under conditions similar to those under which it must work. To prime the pump, it is simply necessary to open the cock, or valve, in the priming pipe and allow water from the column pipe to flow down into the suction pipe and the pump. When these are full, the valve is again closed and the pump is ready to start.

Pumps sometimes fail to raise the water when the full head is resting on the valves in the discharge chamber. This may be due to air accumulating between the suction and the discharge decks, which air is compressed and expanded by the motion of the plunger. Air valves should be provided in the water cylinder for the purpose of allowing this confined air to escape. Violent jarring and trembling often take place if the discharge chamber is not provided either with an air chamber where the lift is not above 150 ft., or with an alleviator, for lifts above that distance. This jarring is due to the column of water in the discharge pipe coming to rest suddenly between strokes and having to be again put in motion.

In case the pump column is filled with water and the pump is stopped, the water will run back through the pump if the foot-valve is not tight. To prevent this, a gate valve or a check-valve is placed a short distance from the pump in the column pipe. A gate valve wears less than a check-valve, and presents no obstruction to the flow of water when the valve is open. This valve is useful in the column pipe to keep the pressure off the valves when the pump is not at work, and also for keeping water from running back into the pump chamber when the valves are being repaired.

When starting compound pumps, the steam on the high-pressure-cylinder piston is not always powerful enough to move the plungers against the resistance of the water in the discharge pipe; but, by opening the gate valve in the by-pass piping, the pressure on the plungers is relieved for a sufficient number of strokes to allow the steam to reach the low-pressure piston, when the

combined force of the two pistons will do the work and the by-pass pipe can be closed.

Valves in the steam end sometimes wear unevenly or the valve stems by continual action wear and cause lost motion, thus causing a back pressure and irregular action. Anything wrong in the steam end can usually be determined by the irregular exhaust, but even this may be deceptive in case the water-end valves are leaking. If the steam valves are suspected, the steam-chest cover may be raised for their inspection, but the valves should not be disturbed until it has been determined, by moving the water piston backwards and forwards several times, that they do not open and close properly. The trouble may be in the levers or toggles that throw them, and the adjustments may be properly made without disturbing the valves. In many duplex pumps, there are very slight differences between the two sides, and the amount of lost motion between the valve stem and the valve should be carefully adjusted. Too little lost motion will cause short stroking, while too much will allow the pistons to strike the heads. The adjustment requires skill.

Sometimes, the valve seat or the valve has soft spots that wear faster than the rest of the valve and seat. Through these slight depressions, steam will blow and cut both valve and seat if attention is not given them; back pressure will then seriously interfere with the working of the pump. If the defect is in the valve, a new one can take its place; but the valve seat, if a part of the steam cylinder, will require an entirely new cylinder, and hence it is economy to scrape the seat until the depressions are removed. A try plate made of steel having a perfectly level surface is covered with chalk and carefully rubbed over the valve seat; the elevations will have chalk on them, the depressions will not. The elevations are scraped with a chisel made of the best steel until they are worn down so that chalk sticks to every part of the seat alike. The valve is treated in the same way if it can be done without too much expense. The valve and the valve seat when removable should be sent to the shop to be reground.

The first step after a pump has been erected is to clean out the steam piping. In order that this may be done without carrying foreign matter into the pump, the piping is left disconnected from the pump and steam at full boiler pressure is allowed to blow freely through the piping and valves for a few minutes. Steam is then shut off and the piping is connected to the pump.

The next step is to blow out the steam cylinders. To do this, the cylinder heads should be put on, leaving the pistons and valves out of the cylinders. The stuffingboxes should be closed, which is most conveniently done by placing a piece of board between the stuffingbox and the reversed gland and then setting up the nut on the stuffingbox studs. When the gland is drawn home by a nut outside of it, a circular piece of pine board may be placed between the end of the gland and the inside of the nut in order to close the opening through which the piston rod passes. Steam may now be turned on the main steam pipe leading to the pump; by opening the throttle valve wide at short intervals, the sand and scale in the ports and other passages and spaces of the steam end can be blown out. After the cylinders have been blown out, the heads and covers should be removed and all foreign matter blown into the corners and chambers of the cylinders removed by hand. The pistons, valves, cylinder heads, and other covers can then be put in place. The blowing out of the pipes and cylinders after erection is often neglected or but imperfectly done, with serious consequences to the machine; it cannot be too thoroughly done, particularly in that type of pump where the steam ports and exhaust ports are on top, for in this particular case the sand and grit are deposited in the bottom of the cylinder for the piston to ride on.

The packing of all rods and stems is the next step. If fibrous packing is used, the boxes should be filled full and the glands tightened down very moderately. The tightening of the glands can best be done when steam is on and the machine is in motion, when they should be tightened only sufficiently to stop leakage and no more. When excessive tightening is required to stop leakage, the packing should be completely renewed. Some pumps are fitted with metallic packing; this packing is usually prepared by specialists and fully guaranteed, and their directions for use should be carefully followed. In case of failure or unsatisfactory results, the makers should be consulted.

The oiling of the machinery is the next step and is a very important one. All rubbing surfaces should be provided with suitable oiling devices appropriate to the particular place and service. The quality of oil should be carefully selected to suit the velocity and pressure of the rubbing surfaces on which it is used. For use within the steam cylinder, heavy mineral oil is the only oil

capable of withstanding the high temperature; and when starting up new pumps only the best quality should be used, regardless of price. A liberal use of this oil for the first month will go far toward reducing subsequent oil bills.

The pumping engine must often run continuously or without interruption for a month or even longer. This requires that all oiling devices be so arranged that they can be supplied and adjusted while the machine is in motion. It is a good plan to provide two sets of oiling systems for all the principal journals, so that if one fails the other can be used while the disabled one is being overhauled. All oil holes are generally stopped with wooden plugs or bits of waste twisted into the hole, or are otherwise protected while the machine is being erected. These should now be removed and the oil holes and oil channels thoroughly cleaned. Bearings should be flooded with oil at first to wash out any dust or grit that may have reached the rubbing surfaces.

The steam end is then ready to be warmed up, and it may be mentioned that from now on the method of starting a pump is the same whether the pump is a new one or an old one. To warm up the steam end, the throttle is opened just a little and with the drain cocks opened wide, steam is allowed to blow through the cylinder until no more water passes out of the drain cocks, using the steam by-pass pipes in case of multiple-expansion pumps. If the pump has a valve gear that can be operated by hand, the warming up can be hastened by working the valve back and forth slowly. While the steam end is warming up, the water end should be made ready by opening the stop-valve in the delivery pipe and otherwise seeing to it that the pump has a free delivery. If a stop-valve is fitted to the suction pipe, this should be opened. If the machine is compound or triple expansion, the water by-pass valves must be opened until the machine has made a sufficient number of strokes to bring the intermediate and low-pressure cylinders into action, when the by-pass valves should be closed. If the pump is fitted with dash-relief valves, these should be closed before starting, in order to keep the pistons as far from the heads as possible in starting. Should the pump exhaust into an independent condenser, this should be started and a vacuum obtained before starting the pumps.

To start the pump, open the throttle slowly and let the pistons work back and forth very slowly a few times, gradually increasing the velocity until full speed is attained. After the pump has been running a few minutes, close the drain cocks. If the pump has dash-relief valves, the length of stroke may now be carefully adjusted.

To stop the pump, close the throttle, open the drain cocks, and close the gate valve in the discharge pipe, if one is fitted. Afterwards, shut down the condenser.

## MISCELLANEOUS FORMS OF WATER ELEVATORS

**Jet Pump.**—In the jet pump, the energy of a jet of water is utilized for raising a larger volume through a small distance, or a mixture of water and solid material through a short distance.

**Vacuum Pump.**—The *pulsometer*, which is the most important representative of the vacuum pumps, consists of two chambers in a large casting, with suitable automatic valves arranged at the top and bottom of the chambers. Steam is introduced into one of the chambers, then the valve at the top closed. This steam will condense, forming a vacuum that draws water from the suction into the chamber. When the chamber is filled with water, steam is again introduced and forces the water out through the discharge pipe. The operation is then repeated, more water being drawn in by the condensation of the steam. The two chambers work alternately, one being engaged in drawing water in while the other forces it out. The total steam efficiency of this form of pump is small, though it may actually be above that of small steam pumps employed in isolated portions of a mine. The advantages are that the pump possesses no intricate mechanism nor reciprocating parts, requires no lubrication, and is not injured by gritty or acid materials. On this account it may be employed for pumping water in concentration works, coal-washing plants, and similar places where the water is liable to contain grit or dirt.

**Air-Lift Pumps.**—By introducing compressed air at the bottom of a pipe submerged in any liquid, the air in the pipe rises as bubbles, and so reduces the specific gravity of the fluid in the pipe. This causes the fluid in the pipe to rise above the level of that surrounding the pipe. The difference in specific gravity can never be great, and hence the fluid can never be elevated to any considerable height without having the lower end immersed to a correspondingly great depth. On this account it is frequently necessary to drill a well

considerably below the water-bearing strata, so as to obtain the proper ratio between the submerged portion of the pipe and the height to which the water is to be lifted. Some advantages of this form of pump are that there are no moving parts, no lubrication is required, and gritty material does not interfere with the operation. If the pump is constructed of suitable material, it may be employed for handling acids or solutions in electrolytic or chemical works. This style of pump is also quite extensively employed for pumping water from Artesian wells. It has not been successful as a mine pump, owing to the ratio between the part immersed and the lift.

**Water Buckets.**—Where only a limited amount of water collects in the mine workings, it is frequently removed by means of a special water bucket or water car during the hours that the hoisting engine would otherwise be idle. Where very large amounts of water are to be removed from deep shafts, it has been found economical to do this with special water buckets.

One of the best illustrations of this class of work is the Gilberton water shaft, which has been equipped at the Gilberton Colliery of the Philadelphia and Reading Coal and Iron Co. The collieries draining to this shaft require the removal of 6,000,000 gal. of water per 24 hr. during the wet season, and this has to be lifted from a depth of 1,100 ft. In order to accomplish the work by means of steam pumps, it required a number of pump stations in different parts of the mine, each of which had to be attended by a pumpman, and a large number of steam lines were required in the mine. In order to remove the danger of fire caused by these steam lines, and to dispense with the large amount of labor otherwise necessary, it was decided to hoist the water, and a shaft 22 ft.×26 ft. 8 in. outside of timbers, was sunk. This shaft contains two compartments 7 ft.×7 ft., in which the water buckets are operated, and two compartments 7 ft.×11 ft. 8 in. that are utilized for cages to lower men, timber, and other supplies. The water tanks employed in the special water compartments are 5 ft. 6 in. in diameter, and 14 ft. long. They are provided with special devices, sliding on regular cage guides, and empty themselves automatically at the surface by means of a trip or sliding valve. Two pairs of direct-acting hoisting engines, with 45-in.×60-in. cylinders, operating drums 14 ft. 8 in. in diameter by 15-ft. face, are employed. These operate the water buckets in cages by means of 2-in. crucible steel ropes, at 50 rev. per min., which is equivalent to a piston speed of 500 ft. per min. The drums will hoist two tanks of 2,400 gal. per min. This gives an output of 7,000,000 gal. per 24 hr. By slightly increasing the speed of the engine, this amount can be increased 10%, which is 25% in excess of the calculated maximum demand on the shaft. The cages in the cage compartments are so arranged that they can be disconnected, and water buckets substituted for them. This would be a total output of over 14,000,000 gal. per 24 hr. at the normal speed of the engine. One great advantage of this style of pumping plant is that there is absolutely no fear of drowning the pumps.

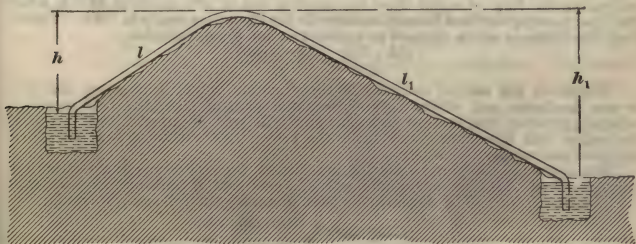
The following figures by Mr. F. E. Brackett give the cost of operation and the efficiency of the water hoist at the Coleman shaft, Cambria County, Pennsylvania. The Coleman shaft is about 660 ft. deep and the water hoist consists of two Wellman-Seaver-Morgan boiler-shaped automatic skips of 1,200 gal. capacity each, with the customary valves, etc. "The bailing of the water was carried on intermittently by the main hoisting engine. It was found that bailing from 20 to 30 min. per hr. was sufficient to keep the water down.

"When bailing with one skip, one skip of water was delivered every 75 sec. but by a slight effort a skip could be delivered in 60 sec. When two skips were in use, the time necessary to deliver a skip was from 31 to 38 sec., averaging 34 sec. Of this time, 20 sec. were occupied in hoisting the skip 700 ft. and the remaining 14 sec. were occupied in slowing down and dumping. The actual dumping only occupied about 5 sec. The capacity of the two skip hoists was, therefore, $(1,200 \div 34) \times 60 = 2,120$ gal. per min.

"The amount of coal consumed in hoisting the 800 gal. per min. made by the mine at this time was 23 gross T. per da. of 24 hr. It was estimated that 85% of this, or 19 T., was consumed in hoisting the water. The consumption of steam by the hoisting engine, as computed from its dimensions, was 74 lb. per useful H. P. per hr. As it requires 141 H. P. to hoist 800 gal. of water per min. 700 ft., the amount of steam required was 250,416 lb. per da. Dividing the water by the coal, the efficiency of the boilers on this kind of intermittent work is only 6 lb. of steam per lb. of coal. The duty of the plant, as computed from these data, is about 15,400,000 ft.lb. of work per 100 lb. of coal, which is extremely low."

Mr. Brackett reaches the conclusion of other mining engineers that water hoisting from shallow depths is very uneconomical "as there is very little opportunity to use the steam expansively. Even should an attempt be made to do so, the time occupied in getting up speed, when the steam must be admitted at nearly full stroke, occupies a large percentage, sometimes all, of the total time under steam. In the second place, there is a large amount of power wasted during every winding by the application of brakes to bring the load to rest. Besides these, the intermittent use of steam necessarily interferes with the economical operation of the boilers. Enough steam cannot be raised during the demand for it without wasting fuel during the time there is little or no demand for it. By careful design, especially on windings of greater length, no doubt these losses can be reduced to some extent, but as a general proposition the plan of hoisting water instead of pumping it should not be adopted, unless there exists some other reason that is of greater weight than the economical side of the question."

Some years ago the Hamilton iron mine, in Michigan, was drowned by a sudden inrush of water that drove the pumpmen from the pumps. In order to remove this large volume of water, special bailing buckets were substituted for the ordinary mine skips. These bailing buckets ran on the inclined skip road, and unwatered the mine in a remarkably short time.



**Siphons.**—The principle on which the siphon works is shown in the accompanying figure. The atmospheric pressure on the surface of the water in the upper basin will force the water up the short leg $l$ to the crown or summit, from whence it will flow by gravity through the long leg $h$ into the lower basin. The vertical height $h$ is called the *lift*, and the vertical fall $h_1$, the *fall* of the siphon. The difference between these heights $(h_1 - h)$ may be called the *siphon head*. The pressure of the atmosphere on the water in each basin acts to keep the pipes $l$, $h$ filled with water.

The conditions required for the successful operation of a siphon may be stated as follows:

1. The height of the summit of the siphon above the surface of the water in the upper basin, or the vertical lift of the siphon, must not exceed a practical limit to which the atmosphere will force the water. This height is theoretically 34 ft. at sea level, but is less at points above the sea level. A safe rule to apply in determining the vertical height to which the atmosphere will force the water in the suction pipe of a pump, or in the short leg of a siphon, is to take .8 of the barometric height, expressed in inches, for the vertical lift of the pump, or siphon, in feet. Thus, if the barometer stands at 30 in., the lift of the pump or siphon, may be taken as $30 \times .8 = 24$ ft. Where the suction pipe is nearly vertical, and consequently of shorter length, this height may be somewhat increased; but where the suction pipe is inclined and its length therefore considerable, the vertical lift should be decreased proportionately.

2. The longer leg, or the discharge pipe of the siphon, must fall through a greater vertical height than the short leg, or draft pipe.

3. When the fall $h_1$ of the siphon exceeds the practical limit to which the atmosphere will force the water, care must be taken to arrange the fall of the siphon relative to its lift, or to increase the length of the long leg, or to use a pipe of a smaller diameter, or to throttle the discharge by means of a valve, so as to prevent the siphon from running empty in a few hours, which it will do whenever the fall is so great that the water in the long leg runs away from the crown faster than the atmospheric pressure forces it up the short leg.

Another important condition requisite to the successful operation of a siphon, is the submerging of both ends of the siphon pipe in their respective basins, in order to prevent air from being drawn into the pipe and reaching the crown, or summit, of the siphon. This takes place more readily in the short leg of the siphon than in the long leg, due to the direction of the flow of the water. The submergence of the discharge end of the siphon, however, is important in order to insure a full flow in the pipe. Air carried into a siphon by the water will gradually accumulate at the highest point of the siphon pipe and will interfere with the working unless an air trap is provided at that point through which the air can be let off from time to time.

In order that a siphon may operate successfully without a throttling valve, its length, diameter, lift, and fall must bear a certain relation to one another, or fulfil certain conditions, without which the pipe has a tendency to empty itself. Referring to the accompanying figure, and calling the head, length, and diameter of pipe, $h$, $l$, and $d$, respectively, on the suction end; and $h_1$, $l_1$, and $d_1$ on the discharge end, as the flow is uniform throughout the pipe,

$$\frac{hd^5}{l} = \frac{h_1 d_1^5}{l_1}$$

But the pressure of the atmosphere acts on both ends; at sea level, this will support a water column of $14.7 \div .434 = 34$ ft., practically. Hence, the head producing the flow of water from the suction end to the crown is $34 - h$, while the head causing the flow from the crown to the discharge end is $h_1 - 34$. Therefore, the formula when applied to siphons at sea level, becomes

$$\frac{(34 - h)d^5}{l} = \frac{(h_1 - 34)d_1^5}{l_1}$$

Whenever the second member of this formula, which represents the flow in the discharge end of the siphon, becomes greater than the first member, which represents the suction end, the pipe will tend to empty itself, because the water will then flow away from the crown faster than the atmospheric pressure can supply the waste.

Whenever the foregoing equation is satisfied, the siphon needs no throttling valve to restrict its flow, although a valve at each end of the siphon is necessary for filling the pipe. The discharge is then given by the following formula,

$$G = 2.83 d^2 \sqrt{\frac{d(h_1 - h)}{f(h_1 + l)}}$$

EXAMPLE.—A siphon pipe 4 in. in diameter and 1,000 ft. long, has a rise of 15 ft. and a fall of 40 ft.; how many gallons of water will it discharge in 1 hr.?

SOLUTION.—Assuming that, for mine work, $f = .01$, and substituting the given values in the formula, $G = 2.83 \times 4^2 \times \sqrt{\frac{4 \times (40 - 15)}{.01 \times 1,000}} = 143+$ gal. per min. The quantity discharged in 1 hr. is then $60 \times 143 = 8,580$ gal.

---

# HEAT AND FUELS

*Heat* is a form of energy produced by the rapid vibrations of the molecules of a body. All bodies are assumed to be built up of molecules that are held together by cohesion but yet are in a state of rapid movement in relation to one another. The application of heat to a body causes a more rapid vibration of the molecules, and the withdrawal of heat causes a less rapid vibration thereof; it is to the rate of vibration that the sense of hotness or coldness is due.

**Thermometers.**—Changes in the temperature of a body are commonly measured by a thermometer, although very high temperatures are measured in other ways as by means of a pyrometer, etc. Because of its uniform expansion and its sensitiveness to heat, mercury is commonly used in the construction of thermometers, provided the temperatures to be measured range between, say, $-35°$ F. and $+625°$ F. This is because mercury freezes at about $-38°$ F. and volatilizes at $+675°$ F., beginning to give off some vapor at even a lower temperature. For measuring temperatures below the freezing point of mercury, alcohol is commonly employed although the United States Bureau of Standards prefers toluene.

In all thermometers, the freezing and boiling points of water under mean atmospheric pressure at sea level determine two fixed points, but the division of the scale between these points is made in one of three different ways. In

the Fahrenheit thermometer, which is in universal use in the United States and Great Britain, the boiling point of water is called 212° and the freezing point 32°, the 0° of the scale being 32° below the freezing point and at what was then supposed to be the lowest temperature attainable. In the centigrade thermometer, in use in those countries that employ the metric system and in England and the United States in scientific work, the freezing point of water is called 0° and the boiling point 100°. In the Réaumur thermometer, in use in Russia and in Germany (for domestic purposes), the freezing point of water is called 0° and its boiling point 80°. The following formulas serve to convert the readings of one scale into those of the others:

$$F° = \tfrac{9}{5} C° + 32° = \tfrac{9}{4} R° + 32°$$
$$C° = \tfrac{5}{9}(F° - 32°) = \tfrac{5}{4} R°$$
$$R° = \tfrac{4}{9}(F° - 32°) = \tfrac{4}{5} C°$$

Thus, 1,000° C. is equal to $\tfrac{9}{5} \times 1,000 + 32 = 1,832°$ F., and, smiilarly, 490° F. is equal to $\tfrac{5}{9}(490 - 32) = 254.5°$ C. However, when the relation between a given number of degrees of the scales is desired other formulas must be used. Because between the freezing and boiling points of water there are 100° on the centigrade scale and 180° on the Fahrenheit scale, 1° C. = 1.8° F., and 1° F. = .555° + C. Thus, a range of temperature represented by 1,000° C. is equal to a range of 1,800° F.

### COMPARISON OF THERMOMETER SCALES

|  | Fahrenheit Degrees | Centigrade Degrees | Réaumur Degrees |
|---|---|---|---|
| Absolute zero | −459.64 | −273.13 | −218.51 |
| Zero, Fahrenheit | 0.00 | − 17.78 | − 14.22 |
| Freezing point | 32.00 | 0.00 | 0.00 |
| Maximum density of water | 39.10 | 3.94 | 3.15 |
| Boiling point | 212.00 | 100.00 | 80.00 |

**Absolute Zero.**—At 32° F., a perfect gas expands $\frac{1}{491.64}$ part of its volume if its temperature is increased 1°, the pressure remaining unchanged. Consequently, at $32° + 491.64° = 523.64°$ the gas will occupy double its original volume; and if the temperature is reduced to $491.64° - 32° = -459.64°$, the gas will disappear. Presumably some change in the rate of contraction takes place before the minimum temperature is reached, but the law may conveniently be used within the range of temperature where it is known to hold good. This temperature of −459.64° F. (commonly taken as −460° F.) is known as *absolute zero*. On the centigrade scale, this point is reached at −273.13°, usually taken as −273°. From this, any perfect gas expands $\tfrac{1}{491}$ or $\tfrac{1}{273}$ of its volume for each 1° increase in temperature above that of absolute zero, depending on whether the Fahrenheit or centigrade thermometer is used.

Temperatures reckoned from the absolute zero are known as absolute temperatures. To find the absolute temperature on the Fahrenheit scale, add 460° to the reading of the thermometer. Thus, 62° F. = 460 + 62 = 522° absolute F., and −54° F. = 460 − 54 = 406° absolute F. Similarly, in the centigrade scale, 62° C. = 273 + 62 = 335° absolute C., and −54° C. = 273 − 54 = 219° absolute C.

**British Thermal Unit.**—The quantitative measure of heat in use by English-speaking nations is known as the British thermal unit, commonly written B. T. U. It is the quantity of heat required to raise the temperature of 1 lb. of water 1° at 62° F.; that is, from 62° to 63°. For accurate work, it is necessary to specify the particular degree at which the temperature is measured for the amount of heat required to raise the temperature of 1 lb. of water is not the same for all parts of the thermometric scale. British thermal units were at one time referred to the temperature of the maximum density of water, 39.1° F., but recent practice uses 62° F. as being nearer the mean value.

The heating value of a fuel is commonly expressed in the number of British thermal units per pound of coal, oil, etc., it will yield on burning. Thus, it may be stated that a certain coal has a fuel or heat value of 12,000 B. T. U.

This means that 1 lb. of the fuel when burned under perfect conditions will yield sufficient heat to raise the temperature of 12,000 lb. of water 1° F., or will raise the temperature of 1 lb. of water 12,000° F.

**Calorie.**—The calorie is the equivalent in the metric system of the British thermal unit. It is the amount of heat required to raise the temperature of 1 kilogram of pure water from 15° to 16° C. As in the case of the British thermal unit, the calorie was at one time referred to as the temperature of water at its maximum density, or 3.94° C. The French and English systems are not exactly equivalent or interchangeable because the quantity of heat required to raise the temperature of a given mass of water from 59° F. (15° C.) to 60.8° F. (16° C.) is not exactly the same as that required to raise its temperature from 62° F. to 63° F. This difference, however, is very little, but .03%.

There are two calories in common use. The one just defined, in which the unit weight is the kilogram, is in use commercially and is known as the *large calorie.* Chemists use the *small calorie*, $\frac{1}{1000}$ of the former, being the amount of heat required to raise the temperature of 1 gram of water from 15° C. to 16° C. These are also known as the *kilogram-calorie* and *gram-calorie,* respectively.

**Pound Calorie.**—The pound calorie is the quantity of heat required to raise the temperature of 1 lb. of water from 15° to 16° C. This unit is not infrequently employed in stating the calorific power or heat value of coals and in metallurgical calculations where the weights of the substances involved are given in pounds.

**Equivalence of Heat Units.**—Neglecting the difference in the specific heat of water at different temperatures (as noted before), the relations between the different thermal units may be determined as follows:

$$1 \text{ B. T. U.} = .252 \text{ large cal.} = 252 \text{ small cal.} = .0555 \text{ lb.-cal.}$$
$$1 \text{ large cal.} = 1,000 \text{ small cal.} = 3.968 \text{ B. T. U.} = 2.2046 \text{ lb.-cal.}$$
$$1 \text{ small cal.} = .001 \text{ large cal.} = .003968 \text{ B. T. U.} = .0022046 \text{ lb.-cal.}$$
$$1 \text{ lb.-cal.} = 1.8 \text{ B. T. U.} = .4536 \text{ large cal.} = 453.6 \text{ small cal.}$$

When calories are expressed per kilogram and it is desired to find the equivalent number of British thermal units per pound, the factor for multiplying is 1.8 as will appear from the following fractions, which show the relation between the units of the two systems:

$$\frac{\text{B. T. U. per lb.}}{\text{Cal. per kg.}} = \frac{\text{lb. raised deg. F.}}{\text{kg. raised deg. C.}}$$

As pounds are in each numerator and kilograms are in each denominator they may be canceled, and $\frac{\text{B. T. U.}}{\text{Cal.}} = \frac{\text{Deg. F.}}{\text{Deg. C.}} = \frac{1.8}{1}$, because 1° F. = 1.8° C. From this B. T. U. (per pound) = 1.8 cals. (per kilo).

**Mechanical Equivalent of Heat.**—Heat being a form of energy is capable of performing work. Joule's investigations showed that 1 B. T. U. was equivalent to 772 ft.-lb. of work, but later determinations indicate that the true mechanical equivalent of 1 B. T. U. is 777.52 ft.-lb., which is commonly taken as 778 ft.-lb. Thus, if 1 lb. of Pocahontas coal has a fuel value of 15,000 B. T. U., it is capable of doing 15,000×778 = 11,670,000 ft.-lb. of work, The unit of work in the metric system is the meter-kilogram (often called the kilogram-meter) and is equal to 1 kg. raised through a height of 1 m. One calorie is equal to 426.8028 m.-kg. One B. T. U. = 107.5614 m.-kg., and 1 cal. is equal to 3,087.3531 ft.-lb. The number 778 is called the mechanical equivalent of heat, or, sometimes, Joule's equivalent.

**Expansion by Heat.**—All bodies change in volume as the temperature to which they are subjected is changed; they commonly expand as they are heated and contract as they are cooled. The rate of expansion is commonly expressed as a coefficient, which indicates the relative amount the substance expands in length for an increase of 1° in temperature. The rate of expansion is not the same at all temperatures, as it increases slightly, in the case of metals, as higher temperatures are reached.

In the first table on page 359 are given the coefficients of linear expansion for 1° F. of some of the more common materials. The coefficients of surface expansion are twice the values in the table; and the coefficients of cubic expansion, or expansion in volume, are three times the tabular values. Thus, a bar of wrought iron 60 in. long, if heated from 60° F. to 460° F., or through 400°, will expand 60×.00000677×400 = .16248 in. In a similar way, a sphere of brass measuring 1,000 cu. in. at 32° F., will have its volume increased by 1,000 ×300×(3×.0000104) = 9.36 cu. in. if heated to 332° F.

## EQUIVALENT TEMPERATURES BY THE FAHRENHEIT AND CENTIGRADE THERMOMETERS

| Degrees Fahr. | Degrees Cent. | Degrees Fahr. | Degrees Cent. | Degrees Fahr. | Degrees Cent. | Degrees Fahr. | Degrees Cent. |
|---|---|---|---|---|---|---|---|
| −459.64 | −273.13 | 2 | 16.7 | 62 | 16.7 | 122 | 50.0 |
| 400 | 240.0 | 3 | 16.1 | 63 | 17.2 | 123 | 50.6 |
| 350 | 212.2 | 4 | 15.6 | 64 | 17.8 | 124 | 51.1 |
| 300 | 184.4 | 5 | 15.0 | 65 | 18.3 | 125 | 51.7 |
| 250 | 156.7 | 6 | 14.5 | 66 | 18.9 | 126 | 52.2 |
| 200 | 128.9 | 7 | 13.9 | 67 | 19.5 | 127 | 52.8 |
| 150 | 101.1 | 8 | 13.3 | 68 | 20.0 | 128 | 53.3 |
| 100 | 73.3 | 9 | 12.8 | 69 | 20.6 | 129 | 53.9 |
| 50 | 45.6 | 10 | 12.2 | 70 | 21.1 | 130 | 54.5 |
| 49 | 45.0 | 11 | 11.7 | 71 | 21.7 | 131 | 55.0 |
| 48 | 44.4 | 12 | 11.1 | 72 | 22.2 | 132 | 55.6 |
| 47 | 43.9 | 13 | 10.6 | 73 | 22.8 | 133 | 56.1 |
| 46 | 43.3 | 14 | 10.0 | 74 | 23.3 | 134 | 56.7 |
| 45 | 42.8 | 15 | 9.5 | 75 | 23.9 | 135 | 57.2 |
| 44 | 42.2 | 16 | 8.9 | 76 | 24.5 | 136 | 57.8 |
| 43 | 41.7 | 17 | 8.3 | 77 | 25.0 | 137 | 58.3 |
| 42 | 41.1 | 18 | 7.8 | 78 | 25.6 | 138 | 58.9 |
| 41 | 40.6 | 19 | 7.2 | 79 | 26.1 | 139 | 59.5 |
| 40 | 40.0 | 20 | 6.7 | 80 | 26.7 | 140 | 60.0 |
| 39 | 39.4 | 21 | 6.1 | 81 | 27.2 | 141 | 60.6 |
| 38 | 38.9 | 22 | 5.6 | 82 | 27.8 | 142 | 61.1 |
| 37 | 38.3 | 23 | 5.0 | 83 | 28.3 | 143 | 61.7 |
| 36 | 37.8 | 24 | 4.5 | 84 | 28.9 | 144 | 62.2 |
| 35 | 37.2 | 25 | 3.9 | 85 | 29.5 | 145 | 62.8 |
| 34 | 36.7 | 26 | 3.3 | 86 | 30.0 | 146 | 63.3 |
| 33 | 36.1 | 27 | 2.8 | 87 | 30.6 | 147 | 63.9 |
| 32 | 35.6 | 28 | 2.2 | 88 | 31.1 | 148 | 64.5 |
| 31 | 35.0 | 29 | 1.7 | 89 | 31.7 | 149 | 65.0 |
| 30 | 34.4 | 30 | 1.1 | 90 | 32.2 | 150 | 65.6 |
| 29 | 33.9 | 31 | −.6 | 91 | 32.8 | 151 | 66.1 |
| 28 | 33.3 | 32 | .0 | 92 | 33.3 | 152 | 66.7 |
| 27 | 32.8 | 33 | +.6 | 93 | 33.9 | 153 | 67.2 |
| 26 | 32.2 | 34 | 1.1 | 94 | 34.5 | 154 | 67.8 |
| 25 | 31.7 | 35 | 1.7 | 95 | 35.0 | 155 | 68.3 |
| 24 | 31.1 | 36 | 2.2 | 96 | 35.6 | 156 | 68.9 |
| 23 | 30.6 | 37 | 2.8 | 97 | 36.1 | 157 | 69.5 |
| 22 | 30.0 | 38 | 3.3 | 98 | 36.7 | 158 | 70.0 |

## COEFFICIENTS OF LINEAR EXPANSION PER 1° F.

| Substance | Coefficient | Substance | Coefficient |
|---|---|---|---|
| Aluminum | .00001140 | Marble | .00000400 |
| Brass | .00001040 | Masonry { from | .00000206 |
| Brick | .00000306 | { to | .00000409 |
| Cement, concrete { from | .00000550 | Mercury | .00003334 |
| { to | .00000780 | Platinum | .00000494 |
| Copper | .00000961 | Porcelain | .00000200 |
| Glass { from | .00000399 | Sandstone { from | .00000400 |
| { to | .00000521 | { to | .00000670 |
| Gold | .00000841 | Steel, untempered | .00000599 |
| Granite | .00000460 | Steel, tempered | .00000702 |
| Iron, cast | .00000587 | Tin | .00001160 |
| Iron, wrought | .00000677 | Wood, pine | .00000276 |
| Lead | .00001580 | Zinc | .00001634 |

It should be noted that if the length of a bar that has been heated is determined, and then its length is found after its temperature has been reduced by the amount it has been heated, the value obtained for the contraction in length will not be the same as first obtained for the expansion. Thus, in the case of the wrought iron bar, its final length is 60.16248 in., the expansion from 60° to 460° being .16248 in. If the same bar is cooled from 460° to 60°, the contraction will be 60.16248 × .00000677 × 400 = .16292 in., or .00044 in. more than the expansion from 60° to 460°.

The reason for this difference is purely a mathematical one. If $C$ is the coefficient of expansion and $T_1$, $T_2$, $L_1$, and $L_2$, are, respectively, the initial and final temperatures and the initial and final lengths, the formula becomes,

$$L_2 = \left[\frac{1 + C(T_2 - 32)}{1 + C(T_1 - 32)}\right] L_1$$

**Conduction of Heat.**—The progress of heat from places of higher to places of lower temperature in the same body is called *conduction*. Good conductors are those through which the heat wave moves rapidly; poor conductors are those in which this movement is slow. The relative heat conductivities of some of the metals are given in an accompanying table.

### RELATIVE HEAT CONDUCTIVITIES OF METALS

| Metal | Conductivity | Metal | Conductivity |
|---|---|---|---|
| Silver | 100.0 | Iron | 11.9 |
| Copper | 73.6 | Steel | 11.6 |
| Gold | 53.2 | Lead | 8.5 |
| Aluminum | 31.3 | Platinum | 8.4 |
| Zinc | 28.1 | Bismuth | 1.8 |
| Tin | 15.2 | Mercury | 1.3 |

A non-conductor is a substance that will not conduct heat. No perfectly non-conducting substances are known, although a number of substances are such poor conductors that they are commonly classed as non-conductors. The metals are the best conductors, silver ranking first, while liquids and gases are very poor conductors. Organic substances, as cotton, wool, straw, bran, etc., and rocks and earths, like magnesia, asbestos, etc., are very poor conductors; this quality is taken advantage of in the manufacture of boiler and steam-pipe coverings.

**Radiation of Heat.**—The communication of heat from a hot body to a colder one across an intervening space is called *radiation*. The best example of radiated heat is that received from the sun. The intensity of heat radiation from a given source: Varies as the temperature of the source; varies inversely

as the square of the distance from the source; and grows less as the inclination of the rays to the surface grows less.

The radiating power of heated surfaces depends greatly on the form, shape, and material of which they are composed. Thus, in the case of a cubic vessel, filled with hot water, having its vertical sides coated, respectively, with polished silver, tarnished lead, mica, and lampblack, the radiating power of the sides was experimentally determined to be as 25 : 45 : 80 : 100. From this, bright surfaces radiate less heat than dark ones having the same temperature.

Those bodies or surfaces that reflect heat readily do not absorb it to any extent, and conversely. Thus, lampblack, which reflects few of the heat rays impinging upon it, absorbs nearly all; and polished silver absorbs but about 2.5% of the heat rays, reflecting 97.5%.

**Specific Heat.**—The specific heat of a substance is the ratio between the quantity of heat required to raise or lower the temperature of that substance 1° and the quantity of heat required to raise or lower an equal weight of water 1°. Thus, if the specific heat of lead is .0299, the amount of heat expressed in British thermal units required to raise a certain weight of this metal 1° will raise the same weight of water only .0299 of 1°, or, what is the same thing, as 1 B. T. U. will raise the temperature of 1 lb. of water 1° F., .0299 B. T. U. will raise the temperature of 1 lb. of lead 1° F.

For strict accuracy, the temperature should be noted at which the specific heat is measured, because it has been found that the specific heat is variable for high temperatures. For ordinary temperatures, however, the values given in the accompanying tables may be considered constant. As stated before, the specific heat of water varies with the temperature.

## SPECIFIC HEAT OF WATER AT VARIOUS TEMPERATURES

| Temperature | | Specific Heat | Temperature | | Specific Heat |
|---|---|---|---|---|---|
| Degrees Centigrade | Degrees Fahrenheit | | Degrees Centigrade | Degrees Fahrenheit | |
| 0 | 32 | 1.0094 | 50 | 122 | .9980 |
| 5 | 41 | 1.0053 | 55 | 131 | .9985 |
| 10 | 50 | 1.0023 | 60 | 140 | .9994 |
| 15 | 59 | 1.0003 | 65 | 149 | 1.0004 |
| 16.11 | 61 | 1.0000 | 70 | 158 | 1.0015 |
| 20 | 68 | .9990 | 75 | 167 | 1.0028 |
| 25 | 77 | .9981 | 80 | 176 | 1.0042 |
| 30 | 86 | .9976 | 85 | 185 | 1.0056 |
| 35 | 95 | .9974 | 90 | 194 | 1.0071 |
| 40 | 104 | .9974 | 95 | 203 | 1.0086 |
| 45 | 113 | .9976 | 100 | 212 | 1.0101 |

## SPECIFIC HEATS OF SOLIDS

| Substance | Specific Heat | Substance | Specific Heat |
|---|---|---|---|
| Aluminum | .2143 | Iron, wrought | .1152 |
| Ashes | .2100 | Lead | .0299 |
| Brass | .0883 | Platinum | .0323 |
| Charcoal | .2410 | Steel, soft | .1175 |
| Copper | .0951 | Steel, hard | .1165 |
| Glass | .1937 | Sulphur | .2026 |
| Ice | .5040 | Tin | .0518 |
| Iron, cast | .1189 | Zinc | .0935 |

## SPECIFIC HEATS OF LIQUIDS

| Substance | Specific Heat | Substance | Specific Heat |
|---|---|---|---|
| Alcohol, 32°......... | .5475 | Petroleum........... | .4980 |
| Alcohol, 176°......... | .6794 | Sea water, 64°....... | .9800 |
| Benzene, 50°......... | .4066 | Sulphur, melted...... | .2350 |
| Benzene, 122°........ | .4502 | Sulphuric acid....... | .3363 |
| Glycerine............ | .5760 | Tin, melted......... | .0637 |
| Lead, melted......... | .0410 | Turpentine, Oil of..... | .4110 |
| Mercury, 32°......... | .0335 | | |

In the table of the specific heats of certain gases, it will be noted that two values are given for these. This is because it requires less heat to raise the temperature of a gas when the volume remains constant than when the pressure is constant and the volume varies.

## SPECIFIC HEATS OF GASES

| Substance | Specific Heat at Constant Pressure | Specific Heat at Constant Volume | Substance | Specific Heat at Constant Pressure | Specific Heat at Constant Volume |
|---|---|---|---|---|---|
| Air............... | .2375 | .1690 | Methane.......... | .5929 | .4505 |
| Carbon dioxide..... | .2170 | .1535 | Nitrogen......... | .2438 | .1727 |
| Carbon monoxide.. | .2479 | .1758 | Oxygen.......... | .2175 | .1551 |
| Hydrogen......... | 3.4090 | 2.4123 | Superheated steam | .4805 | .3460 |

EXAMPLE.—Assuming that all the heat of combustion is utilized, how many pounds of cast iron, which has a specific heat of .1189, may be raised from 60° to 260° in temperature, by the burning of 1 lb. of Pocahontas coal with a heating value of 14,500 B. T. U.?

SOLUTION.—The number of British thermal units required to raise the temperature of 1 lb. of cast iron from 60° to 260° is $(260-60) \times .1189 = 23.78$ B. T. U. As 1 lb. of coal yields 14,500 B. T. U., it will raise $14,500 \div 23.78 = 610$ (about) lb. of cast iron from 60° to 260°.

The specific heat of an alloy or of a mixture of gases, etc., is found by multiplying the percentage by weight of each one of the several constituents by its specific heat and dividing the sum of these products by 100.

EXAMPLE 1.—What is the specific heat of an alloy composed of 21% of copper, 40% of tin, and 39% of zinc?

SOLUTION.—

| | | |
|---|---|---|
| Copper | $21 \times .0951 =$ | 1.9971 |
| Tin | $40 \times .0518 =$ | 2.0720 |
| Zinc | $39 \times .0935 =$ | 3.6465 |
| | 100 | 7.7156 |

Hence, the specific heat is $7.7156 \div 100 = .077156$.

EXAMPLE 2.—What is the specific heat of an afterdamp composed of 4.5% $CO_2$, 1.5% $CO$, 80.0% $N$, and 14% $O$, by weight?

SOLUTION.—

| | | |
|---|---|---|
| $N$ | $80.0 \times .2438 =$ | 19.50400 |
| $O$ | $14.0 \times .2175 =$ | 3.04500 |
| $CO_2$ | $4.5 \times .2170 =$ | .97650 |
| $CO$ | $1.5 \times .2479 =$ | .37185 |
| | 100.0 | 23.89735 |

Hence the specific heat is $23.89735 \div 100 = .2389735$, say, 2390.

**Sensible and Latent Heat.**—The heat that serves only to increase the temperature of a body to which it is imparted, and which may be measured by means of a thermometer, is known as *sensible heat*. For illustration, the heat required to raise the temperature of a volume of water from the freezing point at 32° to the boiling point at 212°, or through 180° is sensible heat. In steam engineering, the amount of heat in the water above that at 32° is commonly called the heat of the liquid.

However, heat may be applied to ice at 32° and to water at 212° without increasing the temperature of either. In the one case the ice is changed to water at the same temperature, 32°, and in the other case the water is changed into steam at the same temperature, 212°. In neither case can the heat added be measured by the thermometer until all the ice is converted into water and all the water changed into steam. This heat that is absorbed in changing the state or condition of a body, which does work in overcoming the cohesion of the molecules, is called *latent heat*. This heat is given up when the body resumes its original liquid or solid state.

The heat absorbed in melting a body is called the *latent heat of fusion* and in the case of melting ice into water is equal to 144 B. T. U. The heat absorbed in changing a body from the liquid to the gaseous state is known as the *latent heat of volatilization*. In the case of water this is called the latent heat of *evaporation*, and is commonly taken as being equal to 965.8 B. T. U. Later investigations by Marks and Davis indicate that the true value of the latent heat of evaporation of water is 970.4 B. T. U. Using the former value, the number of British thermal units required to change 1 lb. of ice at 32° F. into steam at 212° F., may be divided as follows:

$$\begin{aligned}
\text{Latent heat of fusion} &= 144.0 \\
\text{Sensible heat from } 32° \text{ to } 212° &= 180.0 \\
\text{Latent heat of evaporation} &= \underline{965.8} \\
&\phantom{=}\ 1,289.8
\end{aligned}$$

Should the ice have been at a temperature below the freezing point there must be added to the 1,289.8 B. T. U. thus obtained the amount of heat required to raise the ice to the melting point. Thus, if the ice is at 0°, the amount of heat required to raise it to 32° will be equal to $(32-0) \times$ specific heat of ice $= 32 \times .504 = 16.13$ B. T. U., and the total heat required to convert 1 lb. of ice at 0° into steam at 212° will be equal to $16.13 + 1,289.8 = 1,305.93$ B. T. U. Should the water have been at, say, 60°, the total heat required to evaporate it into steam at 212° will be:

$$\begin{aligned}
\text{Sensible heat from } 60° \text{ to } 212° &= 152.0 \text{ B. T. U.} \\
\text{Latent heat of evaporation} &= \underline{965.8} \text{ B. T. U.} \\
&\phantom{=}\ 1,117.8 \text{ B. T. U.}
\end{aligned}$$

In those cases where it is necessary to calculate the heat of formation of steam at a higher temperature than 212°, Regnault's formula may be used. This gives the number of heat units required to convert water at 32° into steam at any temperature, $T$.

$$\text{Heat units} = 1,081.4 + .305\,T$$

EXAMPLE 1.—How many British thermal units are required to convert 1 lb. of water at 60° into steam at 400°?

SOLUTION.—From the formula, heat units $= 1,081.4 + (.305 \times 400) = 1,203.4$ B. T. U. But the initial temperature of the water was 60° or $60 - 32 = 28°$ above the freezing point. Inasmuch as a rise of 1° in the temperature of the water requires the expenditure of 1 B. T. U., 28 heat units must be deducted from the total previously obtained, and the required number is $1,203.4 - 28 = 1,175.4$ B. T. U.

EXAMPLE 2.—How many pounds of water at 60° may be evaporated into steam at 400° by the burning of 1 lb. of Pocahontas coal yielding 14,500 B. T. U. per lb.?

SOLUTION.—From example 1, it will require 1,175.4 B. T. U. to convert 1 lb. of water into steam under the assumed conditions. Consequently, 1 lb. of coal will evaporate $14,500 \div 1,175.4 = 12.3$ lb. of water at 60° into steam at 400°.

## MELTING POINTS AND LATENT HEAT OF FUSION OF METALS

| Metal | Fusing Point Degrees F. | Latent Heat Fusion B. T. U. | Metal | Fusing Point Degrees F. | Latent Heat Fusion B. T. U. |
|---|---|---|---|---|---|
| Aluminum | 1,157 | 180.0 | Nickel | 2,642 | 111.6 |
| Copper | 1,985 | 77.9 | Platinum | 3,227 | 49.0 |
| Gold | 1,946 | 29.3 | Silver | 1,764 | 43.8 |
| Iron, wrought | 2,912 | 126.0 | Sulphur | 237 | 16.8 |
| Lead | 619 | 7.2 | Tin | 446 | 24.9 |
| Mercury | −38 | 5.1 | Zinc | 788 | 40.7 |

The boiling point of water decreases as the altitude above sea level increases, as is shown in an accompanying table.

## BOILING POINT OF WATER AT VARIOUS ALTITUDES

| Boiling Point Degrees Fahrenheit | Elevation Above Sea Level Feet | Atmospheric Pressure Pounds per Square Inch | Barometer at 32° F. Inches | Boiling Point Degrees Fahrenheit | Elevation Above Sea Level Feet | Atmospheric Pressure Pounds per Square Inch | Barometer at 32° F. Inches |
|---|---|---|---|---|---|---|---|
| 184 | 15,221 | 8.20 | 16.70 | 199 | 6,843 | 11.29 | 22.99 |
| 185 | 14,649 | 8.38 | 17.06 | 200 | 6,304 | 11.52 | 23.47 |
| 186 | 14,075 | 8.57 | 17.45 | 201 | 5,764 | 11.76 | 23.95 |
| 187 | 13,498 | 8.76 | 17.83 | 202 | 5,225 | 12.01 | 24.45 |
| 188 | 12,934 | 8.95 | 18.22 | 203 | 4,697 | 12.26 | 24.96 |
| 189 | 12,367 | 9.14 | 18.61 | 204 | 4,169 | 12.51 | 25.48 |
| 190 | 11,799 | 9.34 | 19.02 | 205 | 3,642 | 12.77 | 26.00 |
| 191 | 11,243 | 9.54 | 19.43 | 206 | 3,115 | 13.03 | 26.53 |
| 192 | 10,685 | 9.74 | 19.85 | 207 | 2,589 | 13.30 | 27.08 |
| 193 | 10,127 | 9.95 | 20.27 | 208 | 2,063 | 13.57 | 27.63 |
| 194 | 9,579 | 10.17 | 20.71 | 209 | 1,539 | 13.85 | 28.19 |
| 195 | 9,031 | 10.39 | 21.15 | 210 | 1,025 | 14.13 | 28.76 |
| 196 | 8,481 | 10.61 | 21.60 | 211 | 512 | 14.41 | 29.33 |
| 197 | 7,932 | 10.83 | 22.05 | 212 | 0 | 14.70 | 29.92 |
| 198 | 7,381 | 11.06 | 22.57 | | | | |

**Combustion.**—In dealing with the burning of fuels, whether solid, liquid, or gaseous, combustion may be defined as the rapid chemical combination of carbon, hydrogen, and sulphur, or their compounds, with the oxygen of the air, the reaction being accompanied by the production of light and heat. When the combustible or burnable element unites with all the oxygen it is capable of absorbing, the combustion is perfect; otherwise it is imperfect.

The more common chemical reactions in the burning of fuels are here given. The Roman numerals above the symbols employed in expressing the reaction give the relative volumes of the gaseous substances involved, and the Arabic numerals below the reactions are the approximate molecular weights of these substances. The actual weights concerned in the reactions are proportional to the molecular weights.

In the complete combustion of carbon to carbon dioxide, the reaction is

$$\overset{I}{C} + \overset{I}{O_2} = CO_2$$
$$12 + 32 = 44$$
giving 14,544 B. T. U. per lb. of carbon burned.

In the incomplete burning of carbon to carbon monoxide, the reaction is

$$\overset{I}{2C} + \overset{II}{O_2} = 2CO$$
$$24 + 32 = 56$$
giving 4,450 B. T. U. per lb. of carbon burned.

In the combustion of carbon monoxide to carbon dioxide, the reaction is

$$\overset{II}{2CO} + \overset{I}{O_2} = \overset{II}{2CO_2}$$
$$56 + 32 = 88$$
giving 4,325 B. T. U. per lb. and 347 B. T. U. per cu. ft. of $CO$ burned.

In the complete combustion of hydrogen to form water, the reaction is

$$\overset{II}{2H_2} + \overset{I}{O_2} = \overset{II}{2H_2O}$$
$$4 + 32 = 36$$
giving 62,028 B. T. U. per lb. and 349 B. T. U. per cu. ft. of hydrogen burned.

In the complete combustion of hydrogen sulphide to carbon dioxide and sulphur dioxide, the reaction is

$$\overset{II}{2H_2S} + \overset{III}{3O_2} = \overset{II}{2H_2O} + \overset{II}{2SO_2}$$
$$68 + 96 = 36 + 128$$
giving by calculation 7,459 B. T. U. per lb. and 709 B. T. U. per cu. ft. of hydrogen sulphide burned.

In the complete combustion of methane to form carbon dioxide and water, the reaction is

$$\overset{I}{CH_4} + \overset{II}{2O_2} = \overset{I}{CO_2} + \overset{II}{2H_2O}$$
$$16 + 64 = 44 + 36$$
giving 23,513 B. T. U. per lb. and 1,053 B. T. U. per cu. ft. of methane burned.

In the complete combustion of acetylene to form carbon dioxide and water, the reaction is

$$\overset{II}{2C_2H_2} + \overset{V}{5O_2} = \overset{IV}{4CO_2} + \overset{II}{2H_2O}$$
$$52 + 160 = 176 + 36$$
giving 21,465 B. T. U. per lb. and 1,556 B. T. U. per cu. ft. of acetylene burned.

In the complete combustion of olefiant gas to carbon dioxide and water, the reaction is

$$\overset{I}{C_2H_4} + \overset{III}{3O_2} = \overset{II}{2CO_2} + \overset{II}{2H_2O}$$
$$28 + 96 = 88 + 36$$
giving 21,344 B. T. U. per lb. and 1,675 B. T. U. per cu. ft. of olefiant gas burned.

In the complete combustion of ethane to carbon dioxide and water, the reaction is

$$\overset{II}{2C_2H_6} + \overset{VII}{7O_2} = \overset{IV}{4CO_2} + \overset{VI}{6H_2O}$$
$$60 + 224 = 176 + 108$$
giving 22,230 B. T. U. per lb. and 1,862 B. T. U. per cu. ft. of ethane burned.

In the complete combustion of sulphur to sulphur dioxide, the reaction is

$$\overset{I}{S} + \overset{I}{O_2} = SO_2$$
$$32 + 32 = 64$$
giving 4,050 B. T. U. per lb. of sulphur burned.

The following reactions are important in dealing with fuels, particularly of the gaseous type, as one or all of them are concerned in the manufacture of producer or water gas.

If carbon dioxide is forced through a bed of incandescent coke, it absorbs a certain amount of carbon to form carbon monoxide according to the reaction

$$\overset{I}{CO_2} + C = \overset{II}{2CO}$$
$$44 + 12 = 56$$
This reaction is not accompanied by the generation of heat but by its absorption at the rate of 10,150 B. T. U. per lb. of carbon burned.

If steam is injected into white-hot coke, the vapor is decomposed into carbon monoxide and hydrogen. The temperature must be very high and the steam supply partial, the reaction being

$$\overset{I}{C} + \overset{I}{H_2O} = \overset{I}{CO} + H_2$$
$$12 + 18 = 28 + 2$$
In this case, also, there is an absorption of heat and to the extent of 5,883 B. T. U. per lb. of carbon involved.

If in the last case the steam supply is increased and the temperature lowered, the reaction is

$$\overset{II}{C} + \overset{I}{2H_2O} = \overset{II}{CO_2} + 2H_2$$
$$12 + 36 = 44 + 4$$
In this case the absorption of heat is 6,066 B. T. U. per lb. of carbon consumed.

When using any of the foregoing equations as a basis for calculating the volumes and weights of the gaseous substances entering into a reaction, it must be remembered that the same is assumed to have taken place at standard temperature and pressure, viz.: 32° F., and 29.92 in. of mercury. Further discussion of the nature and products of combustion will be found near the end of this section and in the section on Mine Ventilation.

# FUELS

## FUELS IN GENERAL

Substances that are burned for the purpose of generating heat for commercial purposes are called *fuels*. As regards their physical state they are divided into solid, liquid, and gaseous fuels. The *solid fuels* include wood, charcoal, coal, peat, coke, sawdust, and other substances of vegetable origin. *Liquid fuels* include petroleum and its derivatives, naphtha, gasoline, and other oils, and grain, wood, and denatured alcohol. *Gaseous fuels* include natural gas and various manufactured gases, such as coal gas, water gas, producer gas, coke-oven gas, blast-furnace gas, etc. The products of combustion, or gases, from beehive coke ovens are frequently used for steam raising, but can hardly be called fuels as they contain no combustible constituents, their value being in their actual, sensible heat.

The chief combustible element in all fuels is carbon, which has a heat value of 14,544 B. T. U. per lb. In most solid fuels, carbon chiefly exists as such, but in the liquid and gaseous fuels and to a less extent in coal, it occurs as a *hydrocarbon*, that is, as a gaseous compound of carbon and hydrogen. The heat value per pound of gas is given under the head of Combustion in the discussion of the combustion of the various hydrocarbon gases.

The second important combustible element is hydrogen, which has a heat value of 62,028 B. T. U. per lb. of gas. It exists in the free, or uncombined, state in natural gas and in certain manufactured fuel gases, such as water gas, but is more commonly present in the form of a hydrocarbon, or combined with oxygen to form water. If both hydrogen and oxygen exist in a fuel, it is assumed that all the oxygen is combined with the hydrogen in the form of water, $H_2O$. The hydrogen thus combined has no fuel value and must therefore be deducted from the total amount of hydrogen present in calculating the heating value of the fuel. The hydrogen left after deducting what is combined with the oxygen is called the *available hydrogen*. As the weight of hydrogen in water is one-eighth the weight of the oxygen, the percentage of available hydrogen is obtained from the formula, $h = H - \dfrac{O}{8}$. in which $h$, $H$, and $O$, are, respectively, the percentages of available hydrogen, total hydrogen, and oxygen, in the fuel.

## WOOD AS FUEL

*Wood* is composed of woody fiber, or cellulose, $C_6H_{10}O_5$, which makes up the chief part of its bulk; the constituents of the sap; and water. The most important of the sap constituents is a soluble gum, *lignine*, amounting, on the average, to 13% of the wood. The cellulose and lignine are both combustible, whereas the water is not only not combustible, but its evaporation absorbs a good portion of the heat generated by the burning of the other constituents. Dry wood is, therefore, a much better fuel than undried wood.

Newly felled wood contains from 25 to 50% of water, the amount varying greatly with different kinds, but averaging about 40%. Exposed to the air at ordinary temperatures, wood loses a large part of its moisture and shrinks, reaching a minimum of about 20% of moisture after about 2 yr. of air drying, but it absorbs water and swells in air highly charged with moisture.

Ordinary air-dried wood may be considered as having the following composition: hygroscopic water, 20%; oxygen and hydrogen in the proportion in which they unite to form water, 40%; and charcoal, including 1% of ash, 40%.

The effective value of all kinds of wood per pound, when dry, is substantially the same, and is commonly estimated at 40% of that of the same weight of average coal. In the accompanying tables are given the weight per cord of air-dried woods arranged in the order of their fuel value per cord, the weight of coal equivalent to 1 cord of air-dried wood, and Gottlieb's values for the composition and calorific value per pound of different varieties of wood.

## WEIGHTS PER CORD OF DRY WOOD ARRANGED ACCORDING TO FUEL VALUES

| Wood | Weight Pounds | Wood | Weight Pounds |
|---|---|---|---|
| Hickory (shell bark).... | 4,469 | Beech................ | 3,126 |
| Hickory (red heart).... | 3,705 | Hard maple........... | 2,878 |
| White oak............ | 3,821 | Southern pine........ | 3,375 |
| Red oak.............. | 3,254 | Virginia pine......... | 2,680 |
| Spruce............... | 2,325 | Yellow pine.......... | 1,904 |
| New Jersey pine....... | 2,137 | White pine........... | 1,868 |

## WEIGHT OF COAL EQUIVALENT TO 1 CORD OF AIR-DRIED WOOD

| Kind of Wood | Weight of 1 Cord Pounds | Weight of Coal Equivalent to 1 Cord of Wood Pounds |
|---|---|---|
| Hickory or hard maple............ | 4,500 | 1,800 to 2,000 |
| White oak........................ | 3,850 | 1,540 to 1,715 |
| Beech, red and black oak.......... | 3,250 | 1,300 to 1,450 |
| Poplar, chestnut, and elm......... | 2,350 | 940 to 1,050 |
| Pine, average.................... | 2,000 | 800 to 925 |

## COMPOSITION AND CALORIFIC VALUE PER POUND OF WOOD
*(Gottlieb)*

| Kind of Wood | Composition | | | | | Calorific Value | |
|---|---|---|---|---|---|---|---|
| | C | H | N | O | Ash | Calories | B. T. U. |
| Oak................ | 50.16 | 6.02 | .09 | 43.36 | .37 | 4,620 | 8,316 |
| Ash................ | 49.18 | 6.27 | .07 | 43.91 | .57 | 4,711 | 8,480 |
| Elm................ | 48.99 | 6.20 | .06 | 44.25 | .50 | 4,728 | 8,510 |
| Beech.............. | 49.06 | 6.11 | .09 | 44.17 | .57 | 4,774 | 8,591 |
| Birch.............. | 48.88 | 6.06 | .10 | 44.67 | .29 | 4,771 | 8,586 |
| Fir................ | 50.36 | 5.92 | .05 | 43.39 | .28 | 5,035 | 9,063 |
| Pine............... | 50.31 | 6.20 | .04 | 43.08 | .37 | 5,085 | 9,153 |

It is safe to assume that from 2.25 to 2.5 lb. of dry wood are equivalent in fuel value to 1 lb. of soft (bituminous) coal of average quality and that, as stated, the fuel value of the same weight of different woods is very nearly the same; that is, 1 lb. of hickory is worth no more for fuel than 1 lb. of pine, assuming both to be dry.

The efficiency of wood fuel depends largely on whether it is wet (as cut) or dry and in a measure as to whether it is fired as cord wood, in 4-ft. lengths, or as sawdust or *hogeed wood*, the latter term being applied to the fine and shredded material produced by running slabs and logs through a macerator or hogging machine. Such refuse may contain as much as 60% of moisture and requires that a large combustion chamber be provided as well as a large area of heated firebrick to radiate heat to the fuel in order to evaporate the water. To secure this extra space, extension furnaces are commonly used, and added room in the firebox may be had by dropping the grate to the level of the boiler-house floor with an ashpit below. When cord wood is fired, extension furnaces are not generally necessary, although the grates should be dropped. Babcock

& Wilcox, in "Steam," state that "with proper draft conditions, 150 lb. of this fuel (sawdust and hogged chips) containing about 30 to 40% of moisture can be burned per square foot of grate surface per hour, and in a properly designed furnace 1 sq. ft. of grate surface can develop from 5 to 6 boiler H. P. Where the wood contains 50% of moisture or over, it is not usually safe to figure on obtaining more than 3 to 4 H. P. per sq. ft. of grate surface."

## PEAT AS FUEL

*Peat*, or as it is sometimes called, *turf*, results from the accumulation, in place, of partly decomposed and disintegrated vegetable matter, chiefly of varieties of moss (sphagnum), where the ordinary decay and decomposition of such material has been more or less suspended, although the form and a considerable part of the structure of the plant organs are more or less destroyed. It is found in bogs and marshes, where periodic overflows or times of saturation by water are favorable to the growth of plant life and the preservation of its remains under water. According to its origin and the conditions under which it has accumulated, peat may vary in color from brown to black. In texture it may vary from light, spongy matter, that is porous, coarse, fibrous, or even woody, and easily falls to pieces when dry, to forms that are nearly or quite devoid of structure, and which, when wet, are as plastic as clay, and when dry form dense, hard masses resembling lignite. In all cases peat is nearly or quite saturated with water, containing, under usual natural conditions, from 80 to 95%.

When dry, peat is generally lighter colored than when freshly dug and will usually float if placed in water, although this is not always true of the dark-colored, plastic kinds that are high in ash and when thoroughly dry are as compact and nearly as hard as coal. Except for such types, raw or untreated peat is easily crumbled to powder when handled, and makes bulky and unsubstantial fuel that does not bear transportation well. The name *muck* is commonly applied to black impure peats of the more completely decomposed types.

It is estimated that the 12,000 sq. mi. of workable peat bogs in the United States contain 13,000,000,000 T. of marketable peat. These deposits are mostly found in the colder and moister sections of the country, in New England and westwards from close to the southern boundary of New York nearly to the ninetieth meridian and thence northwards to Canada. This is supplemented by a narrow strip of bog land extending down the Atlantic coast to Florida, includes all of that state, and reaches westwards, probably across Texas, to the Mexican border. Areas of unknown extent are met along the Pacific coast in California, Oregon, and Washington. The Canadian deposits of peat are estimated to cover 35,000 sq. mi.

Peat is commonly prepared by cutting the material (after the bog has been properly drained) into regular shaped pieces somewhat larger than an ordinary building brick, which are subsequently stacked with air spaces between and dried in the open or under sheds. In some cases, the peat is subjected to a process of grinding or macerating and pressing before being pressed into bricks and is known as machine peat, pressed peat, condensed peat, or machine-formed peat. Peat, after being air-dried, may be ground to a powder, further dried, and pressed into briquettes under a pressure of 18,000 to 30,000 lb. per sq. in. Either charcoal or coke may be made from peat in suitably designed furnaces or retorts. In the producer, air-dried peat yields large volumes of fuel gas of the most excellent quality; this seems the most satisfactory use of using it in manufacturing operations.

According to the United States Geological Survey, freshly dug peat from Bethel, Conn., gave by analysis, moisture, 88.72%; volatile matter, 6.54%; fixed carbon, 3.13%; ash, 1.61%; and sulphur (separately determined), .08%. The calorific value of this freshly dug peat was but 927 B. T. U. per lb.

A consignment of compressed or machine peat from near Orlando, Fla., and tested at the St. Louis Exposition contained by analysis, moisture, 21%; volatile matter, 51.72%; fixed carbon, 22.11%; ash, 5.17%; and sulphur (separately determined), .45%. The ultimate analysis of the same peat was carbon, 46.57%; hydrogen, 6.51%; nitrogen, 2.33%; oxygen, 38.97%; ash, 5.17%; and sulphur, .45%. The calorific value of the peat was 8,127 B. T. U. per lb.

As a general rule ordinary air-dried peat has about one-half the fuel value of bituminous coal, say, from 4,000 to 5,500 B. T. U. per lb.; the calorific value of machined peat being much higher. The cost of machine peat will range between $.75 to $1.50 per T., so that in fuel value it is about equivalent to bituminous coal at $3 per T.

# COAL

## CONSTITUENTS OF COAL

*Coal* consists of the finely comminuted remains of vegetable matter that have been preserved, under water, from complete decay. Whether it has resulted from the accumulation of drift material, as at the mouths of large rivers, or from the growth of trees, shrubs, and mosses in place in bogs, is an undecided question. The accompanying table shows the theoretical change from wood to anthracite.

## CHANGES IN CHEMICAL COMPOSITION FROM WOOD TO ANTHRACITE

| Substance | Carbon Per Cent. | Hydrogen Per Cent. | Oxygen Per Cent. |
|---|---|---|---|
| Woody fiber........................ | 52.65 | 5.25 | 42.10 |
| Peat from Vulcaire.................. | 59.57 | 5.96 | 34.47 |
| Lignite from Cologne................ | 66.04 | 5.27 | 28.69 |
| Earthy brown coal.................. | 73.18 | 5.58 | 21.14 |
| Coal from Belestat, secondary........ | 75.06 | 5.84 | 19.10 |
| Coal from Rive de Gier.............. | 89.29 | 5.05 | 5.66 |
| Anthracite, Mayenne, transition formation | 91.58 | 3.96 | 4.46 |

The chemical elements present in coal are the carbon, hydrogen, oxygen, and nitrogen of the original vegetable matter, together with the ash thereof, and some sulphur and phosphorus. There are other elements and their combinations present, but the ones named are those commonly determined by the chemist. The carbon exists separately and, known as *fixed carbon*, is the chief combustible substance in most coals. A certain amount of the carbon is combined with some of the hydrogen in various gases called hydrocarbons. The nitrogen exists as a gas, and while part of the oxygen may also exist as a gas and a small portion is probably combined with the carbon as carbon dioxide, the bulk of it is combined with hydrogen in the proportions necessary to form water. The water is commonly called *moisture*, and the other gaseous constituents are called *volatile matter, volatile combustible matter,* or *volatile hydrocarbons.*

Chemists report the composition of coal in the form either of a proximate analysis or of an ultimate analysis. In the former, the constituents are reported in the various combinations in which they occur in the coal, as moisture, fixed carbon, volatile matter, and ash, the percentages of which should add up 100. Both the sulphur and phosphorus are *separately determined;* that is, their amounts are not included to make up the 100% of the four chief constituents. In an ultimate analysis, the constituents are determined in their elementary or ultimate form and the percentages of carbon, hydrogen, oxygen, nitrogen, sulphur, phosphorus if determined, and ash should add up 100. Numerous comparisons of proximate and ultimate analyses of the same coals are given in an accompanying table.

*Moisture* in coal consists of two portions, first, *surface moisture,* or that which is on the exterior surface of each lump, and which may be dried off in ordinary dry air; second, the *hygroscopic moisture,* or that which is held by capillary attraction in the pores of the coal and can only be driven out of a lump of coal by heating it considerably above 212° F. The percentage of surface moisture that may be held in a pile of coal depends on the size of the pieces; the smaller the coal, the greater is the amount of moisture that it will hold. Thus, buckwheat anthracite, or slack bituminous coal, after exposure to rain, may hold as much as 8 or 10%.

The amount of hygroscopic moisture depends on the kind of coal; thus, anthracite contains practically none, or less than 1%; semibituminous coal rarely over 1%; bituminous coal from Pennsylvania, between 1 and 2%; from Ohio, about 4%; from Illinois, 8 to 14%; while lignite may contain 20% or more. A sample of Illinois coal originally containing 14% of moisture, and thoroughly dried by heating to from 240° F. to 280° F., reabsorbed the same amount of moisture when exposed to ordinary air for 2 mo.

In addition to representing 20 lb. per T. of worthless material for each 1% present, moisture causes an actual loss of heat from the fact that every pound of water has to be evaporated into steam at 212° and the steam then raised to an uncertain temperature, which is approximately that of the fire and may be from 1,500° to 2,500°. Thus, the water contained in a coal analyzing 10% moisture will be 200 lb. per T. and will require to raise it from, say, 60° to 1,500°, 200×[1,117.8+(1,500−32)×.48]=364,488 B. T. U., which is all the heat generated by the combustion of about 33 lb. of ordinary coal having a calorific value of 11,000 B. T. U. per lb.

*Fixed carbon* is the chief heat-producing constituent of coal, and, the amount of impurities remaining the same, the relative heating values of coals are fairly well determined by a comparison of their content of this substance. Although the fixed carbon of a coal evaporates much less water than an equivalent weight of the volatile hydrocarbons when properly burned, in ordinary practice so much of the latter is lost through careless firing or improper furnace construction, that the relative heating value of a coal may be fairly approximated by assuming that the fixed carbon is the only useful constituent.

*Volatile matter* is that part of the coal that is driven off as a combustible gas when the coal is heated. When a large percentage of volatile matter is present, coals ignite easily and burn with a long yellow flame, and, in ordinary methods of combustion, give off dense smoke. The relative proportions of volatile matter and fixed carbon in a coal, other things being equal, determine its adaptability to any particular purpose, as appears under the Classification of Coals.

The volatile combustible matter in coal consists of carbon, hydrogen, and oxygen in various proportions, differing with the character of the coal. It is found that, with the exception of cannel coal, the larger the percentage of volatile matter in a coal, the greater, usually, is the proportion of oxygen in the volatile matter. It also appears that in the semibituminous coals, after deducting as much of the hydrogen as is needed to form water with the oxygen, that is, one-eighth as much as the oxygen, the remainder, or the available hydrogen, is combined with carbon in about the proportion forming methane, or marsh gas, $CH_4$, or three parts, by weight, of carbon to one part of hydrogen; while in the bituminous coals it is combined in about the proportions of five parts, by weight, of carbon to one part of hydrogen. The low heating values per pound of combustible in coals that are high in volatile matter and in oxygen, are thus accounted for.

The following calculations made on coals having the ultimate analyses given in the table on pages 382 to 385 illustrate the increase in moisture and the decrease in available hydrogen and calorific power of American coals in proceeding westwards from the New River field of West Virginia by way of Pittsburg, Pa., to Illinois.

No. 114, New River, available $H = 4.66 − \dfrac{4.13}{8} = 4.14$; B. T. U. = 14,765

No. 85, Pittsburg, available $H = 4.63 − \dfrac{7.47}{8} = 3.70$; B. T. U. = 13,952

No. 28, Illinois, available $H = 5.44 − \dfrac{18.71}{8} = 3.10$; B. T. U. = 10,719

The *ash* of coal comes partly from that properly belonging to the vegetable matter from which it was formed and partly from sediments washed into the coal swamp during times of flood. Just what proportion of coal ash represents that of the original plant growth will, naturally, depend on the composition of that growth, something impossible to determine, but it would seem that any ash in coal to the extent of more than 2%, is due to extraneous mineral matter. In composition, coal ash approximates that of fireclay, with the addition of ferric oxide, sulphate of lime, magnesia, potash, and phosphoric acid.

White-ash coals are generally freer from sulphur than red-ash coals, which contain iron pyrites, but there are exceptions, as in a certain Peruvian coal, which contains more than 10% of sulphur and yields not a small percentage of white ash.

The fusibility of ash varies according to its composition. It is the more infusible the more nearly its composition approaches fireclay, or silicate of alumina, and becomes more fusible with the addition of other substances, such as iron, lime, etc. Coals high in sulphur usually give a very fusible ash, on account of the iron with which the sulphur is in combination. A fusible ash tends to form a clinker on the grate bars, and therefore is objectionable.

The quantity of ash in different coals as they are sent to market differs greatly according to the quality of the coal itself and the care taken to remove the slate, dirt, etc. that accompany them as they come from the mine. A lump of coal may contain only 5% of ash, while the average of the coal, including slate and dirt as it is mined, may contain 15%. A considerable part of the slate may be removed from the larger sizes by picking after screening, and from the smaller sizes by washing.

In the case of anthracite, the table on page 386 brings out the increase in ash and decrease in calorific power as the sizes grow smaller. The table on page 387 is of value in showing the actual commercial ash present in bituminous coals, many of which, in the case of carefully selected lumps, will yield by analysis less than one-half the ash given in the table.

*Sulphur*, having a calorific value of 4,050 B. T. U. per lb., is always present in coal. While some few coals, notably the Georges Creek-Cumberland semibituminous, occasionally contain but a trace of this element, it is commonly present to the extent of .5 to 5% and even more. Sulphur is generally classed as an impurity in coals because of the corroding action of its fumes upon metals. The terms *low sulphur* and *high sulphur* as applied to coals, are generally relative, although a coal containing less than 1% sulphur would everywhere be placed among the former and one having 5% among the latter. The amount of this element that will render a coal unfit for any particular service is discussed under the Classification of Coals.

Sulphur occurs in coal in at least three forms. It usually occurs in combination with iron as the bisulphide, $FeS_2$, which is known by various names as fool's gold, brasses, etc., and very commonly only as sulphur. In pyrites, sulphur has about one-half the heating value per pound of carbon. The pyrites may occur in minute crystalline grains disseminated through the mass of the coal or segregated in small patches upon the cleavage planes; as sheets or plates, of considerable area in proportion to their thickness, that are parallel to the bedding; as regular layers interstratified with the coal; and as lense-shaped masses, sometimes weighing 100 lb., known as *sulphur balls*. Sulphur balls, when pure, contain 53.33% sulphur and are a source of income at some mines where they are placed in the gob and from time to time gathered up and shipped to the chemical works, where they are employed in the manufacture of sulphuric acid.

Sulphur may be present as a sulphate, usually that of calcium or lime, $CaSO_4$, less commonly as magnesium sulphate, $MgSO_4$, and sometimes as the salt of other metals. The sulphates are commonly found in thin whitish or grayish plates on the vertical joint planes of the coal; in this combination, sulphur has no fuel value.

Sulphur may also be present in combination with the organic constituents of the coal, in which form it is known as *vegetable sulphur* and has a fuel value.

*Phosphorus*, as a natural constituent of the original vegetable matter, is always found in coal. The amount of phosphorus is always very small and does not affect the heating value of the coal, and is only of importance if the coal is destined to make coke for use in furnaces working on Bessemer iron. Phosphorus probably exists as a single or double phosphate of lime and alumina. Mr. Charles Catlett notes, in the Big seam near Columbiana, Ala., the existence of light-colored, resinous grains of evansite, hydrous aluminum phosphate, $Al_6P_2O_{15}.18H_2O$.

Phosphorus is commonly segregated near both the roof and floor of the seam and by rejecting a few inches of the top and bottom coal, the coke made of the remainder may often be brought within the Bessemer limits. Its amount also varies as the workings are extended and analyses of the coal should be made weekly or monthly as the headings advance.

## CLASSIFICATION OF COALS

The most convenient commercial classification of coals is based on the relative amounts of combustible matter therein, both fixed carbon and volatile hydrocarbons, as determined by a proximate analysis; this is shown in the accompanying table.

It must be remembered that this classification is decidedly arbitrary and that the coals of any one group overlap at either end of the scale into those of the other groups. This is particularly true of the lignites, many varieties of which cannot be distinguished from bituminous coal of the better grades if the proximate analysis is made the criterion. Many of the coals of Arkansas are low in volatile matter and may be grouped with either the semianthracite or semibituminous. Similarly, the low-volatile coals of, say, Somerset County

## CLASSIFICATION OF COALS BASED ON THEIR CONTENT OF FIXED CARBON AND VOLATILE MATTER

| Kind of Coal | Fixed Carbon Per Cent. | Volatile Matter Per Cent. |
|---|---|---|
| Anthracite................................... | 97.0 to 92.5 | 3.0 to 7.5 |
| Semianthracite............................... | 92.5 to 87.5 | 7.5 to 12.5 |
| Semibituminous............................... | 87.5 to 75.0 | 12.5 to 25.0 |
| Bituminous, Eastern United States............. | 75.0 to 60.0 | 25.0 to 40.0 |
| Bituminous, Western United States............. | 65.0 to 50.0 | 35.0 to 50.0 |
| Lignite or brown coal........................ | under 50 | over 50 |

and Cambria County, Pa., may be classed as either bituminous or semibituminous.

Owing to this overlapping of the different groups in the scale, a classification based on calorific values is also unsatisfactory. Likewise, geological age fails to furnish a satisfactory basis of classification. As a general rule, the younger the coal geologically, the higher is its content of moisture and volatile matter and, consequently, the lower is it in fixed carbon. Thus, the coals of the Tertiary age are all lignites and commonly of the brown-coal type; the coals of the underlying Cretaceous are commonly black lignites (subbituminous) with some true bituminous coals among them; and the true bituminous, semibituminous, semianthracite, and anthracite coals are almost entirely confined to the true coal measures of the Carboniferous age, in which, the lower volatile coals are found near the base of the series. This rule appears to hold good in regions where the rocks have either remained undisturbed or at best have been but slightly folded, but metamorphism has played an important part in changing the characteristics of seams in mountain districts. The Cretaceous of Colorado is marked by beds of subbituminous lignite and bituminous coals in the level country and foot-hills, which the metamorphism incident to mountain building has altered to anthracite in the midst of the Rockies; therefore, the same seam may present the characteristics of bituminous coal in flat unbroken regions, of semibituminous coal in the foot-hills, and of semianthracite and possibly of true anthracite in the higher and more disturbed mountains.

**Anthracite.**—Anthracite, or *hard coal*, as it is frequently called, is the densest, hardest, and most lustrous of all varieties. It has a conchoidal fracture, frequently displays iridescence, and is characterized both in the lump and in the bed by the absence of cleavage planes. Its specific gravity ranges from 1.3 to 1.8 with an average value of about 1.5. It contains from 3 to 7% of volatile matter, does not coke, is kindled slowly and with difficulty, requires a strong draft through the firebox, and burns with a short almost colorless flame, which is smokeless or essentially so. Practically all the anthracite mined in the United States comes from a small area in northeastern Pennsylvania. A series of analyses of anthracite from that state are given in the table on page 386. These are commercial analyses made on large shipments and show that on account of the uniformly high ash content, the calorific value of anthracite is rather low in comparison with standard bituminous coals. It will also be observed that the smaller sizes (pea, barley, rice, etc.) are much less efficient than the larger broken, egg, and the like. The high content of ash in the smaller sizes is due very largely to imperfect preparation.

An analysis of the so-called anthracite from Cranston, R. I., is No. 92 of the table on pages 382 to 385. The coal is highly graphitic in character and of far more geological interest than commercial value. Its existence has been known for many years, during which time the numerous attempts to exploit it have always ended in failure.

An analysis of anthracite from the Cretaceous seam near Crested Butte, Colo., and from the same formation at Madrid, N. Mex., are given in the table on page 387.

Analyses of anthracite from Alaska will be found in the table on page 390, from New Zealand in the table on page 391, and of the so-called anthracites (more properly semianthracites) from Banff, Alberta, Canada, in the table on page 388.

In the Pocono formation of the Subcarboniferous in the Sleepy Creek and Third Hill Mountains of Berkley and Morgan Counties, W. Va., are found a series of deposits of anthracite that are so irregular in thickness, uncertain in area, and so crushed and otherwise disturbed as to be commercially worthless. Their content of volatile matter is about 10%, which more properly groups them with the semianthracites.

The so-called anthracites of Blacksburg, Montgomery County, W. Va., an analysis of which is No. 105 of the table on pages 382 to 385, are really semi-anthracites and commercially, are of but little more value than those from Sleepy Creek Mountains, W. Va., or Cranston, R. I.

**Semianthracite.**—Semianthracite contains 7.5% to 12.5% of volatile matter and passes by insensible gradations on the one hand into anthracite and on the other hand into semibituminous coal. It is not so hard or dense as true anthracite, is not so lustrous, and, when freshly broken, will leave soot upon the hands, something anthracite will not do. It is somewhat lighter than anthracite, ignites quite readily, and burns more freely than hard coal.

A series of proximate analyses of Pennsylvania semianthracites mined in the northward extension of the anthracite region is given in the table on page 386. The average of eleven analyses of semianthracite from Alaska will be found in the table on page 390, and an analysis of this grade of coal from Banff, Alberta, Canada, is given in the table on page 388. Several proximate analyses of semianthracite from Arkansas, and one from Virginia will be found in the table on page 387, and complete analyses and calorific values of the same in the table on pages 382 to 385.

**Semibituminous Coals.**—The semibituminous coals containing from 12.5 to 25% of volatile matter, and, neglecting the ash and moisture, from 75 to 87.5% of fixed carbon are everywhere the favorites for steam raising. Typical examples are the well-known Pocahontas and New River coals of West Virginia, the Georges Creek-Cumberland coal of Maryland, the Broad Top coals of Pennsylvania, and the Kittanning coals of Cambria, Clearfield, and Somerset Counties in the latter state. All these coals contain about 18% of volatile matter, from 5% to 10% of ash and water and from 70 to 80% of fixed carbon, with sulphur little if any over 1% and have a calorific value of 14,000 B. T. U. per lb., in some cases even more. Some of the coals in this group are fairly hard and blocky, a structure noticeable in those from the Pittsburg seam in the Georges Creek-Cumberland and Broad Top regions, while others are very soft, as typified in the Pocahontas and New River coals. The Kittanning coals of Pennsylvania are intermediate between the Pocahontas and Georges Creek in hardness. Containing more volatile matter than anthracite, these coals kindle more readily and burn more rapidly with a steady fire.

Complete analyses and calorific values of these coals from Arkansas (so-called semianthracite), Pennsylvania, Maryland, West Virginia, and Oklahoma are given in the table on pages 382 to 385. Other, and shorter analyses of these coals from Maryland, Pennsylvania, and West Virginia are given in the table on page 387. Coals of this type from Alaska are noted in the table on page 390, and some foreign and Canadian semibituminous coals are listed in the tables on pages 388 and 389, respectively.

**Bituminous Coals.**—The bituminous coals include about 75% of the output of the mines of the United States. Those produced in the eastern states contain from 25% to a maximum of 40% of volatile matter, or, say, 30 to 32% as an average. Those mined in the central basin and west thereof range as high as 50% in volatile matter, a general average being about 40%. The western bituminous coals are generally characterized by a very much higher content of water than their eastern namesakes, which frequently runs up to 10%, and usually contain more sulphur. These coals vary from hard to soft and from blocky to columnar in structure. Their specific gravity is normally about 1.3. They burn with a yellow flame and much smoke, and, on distillation, yield hydrocarbon oils, tar, etc. According to the use to which they are put or to certain physical and chemical characteristics, they are subdivided into numerous groups.

**Subbituminous Coals.**—The very convenient term subbituminous coals, which originated with Dr. M. R. Campbell, of the United States Geological Survey, is given to that large and valuable group of coals, that possesses some of the undesirable features of the true lignites or brown-coals, together with many of the desirable features of the true bituminous coals. They are sometimes called *black lignites* from their color, which is often highly lustrous and not to be distinguished from that of bituminous coals proper. They have a

brown streak and a specific gravity of 1.22 to 1.25. They burn with a long, bright flame, with considerable smoke like bituminous coals but do not coke. In composition and calorific power, they closely resemble and are, in some cases, even superior to, the true bituminous coals of the Central Basin, as will be seen by comparing the analyses, in the table on pages 382 to 385 of subbituminous coal No. 14, from Lafayette, Colo., or No. 125, from Hanna, Wyo., with analysis No. 28, of bituminous coal from Livingston, Ill., or with No. 35, from Linton, Ind.

The distinction between the two groups lies in their different behavior on weathering. True bituminous coals break down under atmospheric action into smaller and smaller cubes or prisms, the faces of which are more or less parallel to the cleavage planes (butt, face, etc.) of the coal in the bed. As Doctor Campbell remarks, "Exception is to be noted, however, in the case of cannel coal, splint coal, and many forms of block coal, of which the Brazil block of Indiana may be considered the type. Such coals always show cleavage faces on large blocks, but the blocks do not split readily. These coals generally have other characteristics by which they may be identified without recourse to their weathering properties."

On the other hand, subbituminous coal, on weathering, breaks up into irregularly shaped fragments, and, in particular, separates along the bedding planes into plates. This latter peculiarity is the sole distinction between the two groups of coals. To quote further from Doctor Campbell: "In applying these criteria (weathering, etc.) some coals will be classed as bituminous which have a brown streak, are young geologically, and generally have been regarded as lignites or lignitic coals; but they resist the weather, stand shipment well, and have a high calorific value, which makes them to all intents and purposes bituminous coal."

**Lignite.**—Primarily, the distinction between subbituminous coal and lignite is one of color alone; the former is black and the latter brown. As the subbituminous coals have been segregated from the lignites and given a distinctive name, the original term is now confined to the typical lignite, or brown-coal. Lignites are generally inferior as fuels, compared to the subbituminous coals, are usually higher in moisture and volatile matter and lower in fixed carbon, usually show their vegetable origin more plainly, weather more rapidly, and are less well adapted to transportation. It should be noted that many subbituminous coals and lignites, even in the dry climate of the Rocky Mountain region where they are largely mined, will completely disintegrate into slack within 2 to 4 mo.

Bituminous coals, for trade purposes, are subdivided into many groups with distinctive names, depending on the use to which they are put or to which they are best adapted, or depending on some peculiarity of structure or composition. Some of these varieties are here noted.

**Gas Coals.**—The coals suitable for the manufacture of illuminating gas in closed retorts by the destructive distillation of the coal itself without the admission of either air or steam are termed gas coals. These coals yield the original type of gas used for lighting, a type now quite largely superseded by water gas made by forcing steam through incandescent anthracite or coke. Probably the best, and, in any event, the earliest used gas coals in the United States are those mined along the line of the Pennsylvania Railroad near Irwin and along the Baltimore & Ohio Railroad on the Youghiogheny River, in Westmoreland County, Pa. As there produced, these coals commonly contain as much as 37% of volatile matter, from 6 to 8% of ash with considerably less than 1% of sulphur, and being hard and blocky, bear transportation well. Their yield is rather more than 10,000 cu. ft. of gas per T. of coal charged into the retorts, the gas being of 17 to 21 c. p. The residual coke amounts to about 60% of the weight of the original coal and is shiny, fairly strong, and well adapted to domestic purposes or steam raising. Their yield of nitrogenous products, such as ammonia, is also high. These characteristics of Westmoreland coal, particularly the low content of sulphur, are those demanded of standard gas coals.

**Domestic Coals.**—The term domestic, as applied to coal, refers as much to its size as to its composition or other features. In the anthracite consuming sections of the eastern states, the domestic sizes are stove and chestnut adapted to burning in ranges and small heaters, and egg suitable for use in furnaces. In the bituminous regions, there is frequently sold a domestic lump, which may mean a coal specially screened over bars, say, 3 in. apart, or it may refer to coal that will pass over a 3-in. bar screen and through one with bars set, say, 6 in. apart. In any case, coals for domestic use are well screened and

usually over bars much more widely spaced than those used in preparing coal for steam raising. While it is true that domestic coals are classified more by size than anything else, the possession of certain qualities will make one coal more desirable than another for household purposes. The coal that sustains a mild, steady combustion, and remains ignited at a low temperature with a comparatively feeble draft, is the best. A coal burning with a smoky flame is objectionable as producing much soot and dirt, especially for open grates or cooking purposes. For self-feeding stoves, or for base burners, a dry non-coking coal is necessary. A very free and fiercely burning coal is not desirable, particularly in stoves, as the temperature cannot be easily regulated. A sulphurous coal is also bad, as it produces stifling gases with a defective draft, and corrodes the grates and fire-bowls. The difficulty from clinkering is not so great in domestic uses, as the temperature is not generally high enough to fuse the ash. A stony, hard ash that will not pass between the grate bars is bad, and light pulverulent ash is best.

**Blacksmith, or Smithing, Coals.**—A coal suitable for blacksmith purposes should have a high heating power, should contain as much less than $1\%$ of sulphur as possible, should be low in ash, and should coke sufficiently to form a hollow fire, that is, should form an arch on the forge. The semibituminous coals from the New River and Pocahontas regions of West Virginia, that from the Georges Creek-Cumberland district of Maryland, and the Broad Top (Huntingdon County) field of Pennsylvania, make excellent blacksmith coals as mined. The slack of many coking coals, if washed to reduce the content of sulphur (especially) and ash, serve excellently as smithing coal. The best known blacksmith coal of the east and one formerly used for this purpose to the practical exclusion of all others is known by the name of Blossburg from the town of that name in Tioga County, Pa., where it was first mined. An average analysis of this coal (commercial sample) from the Morris Run mines, where the coal is at its best gave moisture, $1.12\%$; volatile matter, $18.57\%$; fixed carbon, $72.10\%$; ash, $7.63\%$; and sulphur, $.583\%$. It will be noted that this is a semibituminous coal essentially the same as those already described.

**Steam Coals**—In the Eastern states and where anthracite is concerned, the term steam refers entirely to the size of the fuel. Thus, if (as noted under that title) the domestic sizes of anthracite are chestnut, stove, and egg, the steam sizes are smaller than these and include pea, buckwheat, barley, rice, etc. The term steam coal is also often used to indicate any coal, anthracite or bituminous, that is too poor to be used for any purpose except steam raising; the idea being that anything that will burn is good enough to find place in the firebox.

For steam making, the superiority of coals high in combustible constituents is admitted, and those with the higher percentage of fixed carbon are the most desirable. But the consideration of the steaming qualities of a coal involves, also, a consideration of the form of furnace and of all the conditions of combustion. The evaporative power of a coal in practice cannot be stated without reference to the conditions of combustion, and every practical test of a coal, to be thorough, should lead to a determination of the best form of furnace for that coal, and should furnish knowledge as to what class of furnaces in actual use such coal is specially adapted. It is not sufficient that in comparative tests of coals the same conditions should exist with each, but there should also be determined the best conditions for each coal.

Of coals high in fixed carbon, the semianthracites and the semibituminous rank as high as the anthracite in meeting the various requirements of a quick and efficient steaming coal.

For railway use, these coals have been found to excel anthracites in evaporating power. The comparative absence, in semibituminous coals, of smoke, which means loss of combustible matter as well as discomfort to the traveler, is sufficient to suggest their superiority over bituminous coals for such use.

Steaming coal should kindle readily and burn quickly but steadily, and should contain only enough volatile matter to insure rapid combustion. It should be low in ash and sulphur, should not clinker, and when it is to be transported should not easily crumble and break.

**Coking Coals.**—Coking coals are those that become pasty or semiviscid in the fire and produce, if the burning or heating is carried on with the partial or entire exclusion of air and the process is not allowed to proceed too far, a hard or porous mass known as *coke*, which consists, essentially, of the fixed carbon and the ash of the original coal, the peculiar structure being due to the escape from the partly melted mass of individual bubbles of gas driven off by the heat.

Commercial coke making is carried on in firebrick structures known as *coke ovens*, which are of two general and very distinct types. The original form of oven and still the chief type used in the United States consists of a hemispherical shell of firebrick into which air sufficient to burn the escaping gases is admitted over the door during the coking process. This is called, from the marked similarity in form, a beehive coke oven. The modern type, called a retort oven, usually consists of a long (18 to 40 ft.) and narrow (18 to 30 in.) rectangular chamber placed like a book on edge, the height being 10, 12, or more ft. In this chamber the coal is heated without access of air, the process being analogous to the production of illuminating gas. Ovens of this type are frequently called *by-product ovens* as they are well adapted to the recovery from the gases of the tar, ammonia, etc., which are commonly wasted in coking in the beehive oven.

Neither anthracite nor semianthracite on one end of the scale will coke, nor will the subbituminous and lignite coals on the other. This limits the possible possession of coking qualities to the semibituminous and bituminous coals, ranging from 12.5 and 50% in volatile matter. In the United States, those semibituminous coals so low in volatile matter as to approximate the semianthracite in composition either will not coke at all or but very indifferently. The same is true at the other end of the scale of the bituminous coals very high in volatile matter, as these coals in the Western states are almost invariably non-coking. The difficulty in making any coke at all, or at best but a very indifferent one, from Western bituminous coals seems to be due to the large amount of water they contain. Probably 90 or 95% of American coke is made from coal containing between 18 and 35% of volatile matter. But all coals falling within these limits will not coke, and the reason why, of two coals having essentially the same analytic composition, one should coke and the other not, is a much disputed question.

Even if a coal will make some kind of a coke, whether this is of value or not depends on the use to which it is to be put. For the manufacture of pig iron in the blast furnace, the coke must be firm and tough and not dense, but with a pronounced cellular structure and a hard cell wall. If the pig iron from the blast furnace is to be used in the manufacture of steel by the Bessemer process, the makers prefer a coke containing from 1 to 3% of volatile matter and moisture combined, 10 to 12% of ash, and 89 to 85% of fixed carbon with sulphur and phosphorus not over 1% and .02%, respectively. This is the composition of the standard so-called Bessemer coke. Unfortunately, very little coke is now obtainable that possesses both this purity and the proper physical qualities. The objection to sulphur in the coke is that it enters the iron and, not being removed in the Bessemer converter, remains in the steel, which it makes *red short* or brittle when hot. Similarly, phosphorus is not removed in this process, but it makes the steel *cold short*, or brittle when cold, a very serious objection in structures subject to shock, as rails. Further, low-phosphorus iron ores are becoming more and more difficult to obtain, so that the lower the content of this impurity in the coke, the higher may it be in the ore. If the pig iron is to be used for making steel by the basic open-hearth process, phosphorus and to a less extent sulphur are not so objectionable in the coke, as they are largely removed in the furnace.

For use in the foundry in the manufacture of castings, the coke should possess the same physical qualities demanded of good blast-furnace coke, but the percentage of both sulphur and phosphorus may be much higher. In fact, many foundry managers prefer a high phosphorus coke, as the presence of this element in the metal makes it very fluid when melted so that it readily fills the smallest openings in the mold. It is generally demanded that coke for foundry purposes shall be capable of melting 10 lb. of iron per pound of fuel. Such a result is not often obtained and in ordinary practice 1 lb. of coke will melt but 8 lb. of iron.

In smelting operations where the metals are recovered as matte (sulphide of iron, etc.) large amounts of sulphur in the coke are not objectionable, as the element is essential to the process.

For domestic use, it is desirable that the coke be hard so that it will bear crushing and screening to the proper sizes and subsequent transportation to market. The amount of sulphur and phosphorus in domestic coke is not of great importance, but the percentage of ash should be as low as is consistent with due strength, and the ash should not clinker.

From the foregoing, it is evident that a coal that will make a coke suitable for one purpose will not make a coke suitable for another. The fusibility of the carbon, the amount of disposable hydrogen, the tenacity with which the

gaseous constituents are held, the amounts of sulphur and phosphorus in the coal, the rapidity and temperature of the coking process, the state of the coal when charged into the oven (whether as run of mine or slack), even the process itself, all affect in one way and another the physical and chemical qualities of the coke and, consequently, the use to which it is best adapted. More or less weathered coal from near the outcrop will not make as good coke as that mined under more cover; many coals that will coke but indifferently as run of mine coke excellently in the fine state; and others, which make a poor showing in the beehive oven, are well adapted to use in retort ovens.

Ordinary analyses do not indicate whether or not a coal is a good coking coal, and they indicate simply by giving the amount of carbon, ash, and sulphur, what will be the probable purity of the coke formed. To produce a standard Bessemer coke in the beehive oven, the typical coal has essentially the analysis of No. 18, of the table on pages 382 to 385, mined from the Pittsburg seam in the Connellsville region of Pennsylvania. Other analyses of this seam show the volatile matter to be as high as 32%, with the fixed carbon, ash, and sulphur as low as 59%, 7%, and .5%, respectively. Coals having analyses that differ materially from this give most excellent cokes that are in every way equal to that from the Connellsville region. As illustrations of this may be cited the cokes made from the semibituminous coals from the New River and Pocahontas fields of West Virginia, which coals contain only about 18% of volatile matter, as well as coke made from the coal mined from the Freeport seam, which often contains over 35% of volatile matter. Coke made from coals containing less than 5 or 6% of ash, while pure, is not generally desirable as blast-furnace fuel, as it lacks the strength to support the burden, and breaking up before burning tends to be blown out the stack by the blast. It must be remembered that coals that will not yield a satisfactory coke from either the chemical or physical view point in the beehive oven, often will do so in the retort oven. Thus, when investigating the coking qualities of the coal from any field carload lots should be shipped to both beehive and retort oven plants for tests under actual working conditions.

**Yield of Coke.**—There are several methods used by field engineers in arriving at an estimate of the quantity and quality of coke that a given coal will produce. It is obvious that if there is no loss of fixed carbon in the process, all this element will be in the coke together with all the ash. In the Connellsville region, it is found that about 40% of the sulphur is volatilized, 60% remaining in the coke. With this understanding, what is called the theoretic coke obtainable from a coal such as No. 85 from Connellsville may be figured as follows:

|  | Original Coal | Remaining in Coke | Analysis of Coke |
|---|---|---|---|
| Moisture | .97 |  |  |
| Volatile matter | 29.09 |  |  |
| Fixed carbon | 60.85 | 60.85 | 87.00 |
| Ash | 9.09 | 9.09 | 13.00 |
|  | 100.00 | 69.94 | 100.00 |
| Sulphur, separate | .90 × .60 | .54 | .77 |

The figures in the third column are arrived at by dividing those in the second column by .6994, which figure is often spoken of as the *theoretic yield* and which means simply, that the coal in question should yield under perfect conditions 69.94% of its weight as coke, which should have the composition given in the third column. These results agree very closely with those obtained in actual practice in the Connellsville region; in fact, there is frequently a greater yield than the theoretic one due to the deposition of carbon in the pores of the coke during the process.

Many engineers assume that under average conditions 1.5 T. of coal are required to make 1 T. of coke, and that there is enough sulphur volatilized to insure that the percentage of this impurity in the coke shall not exceed that in the original coal. Using the foregoing coal, the figures follow:

|  |  | Analysis of Coke Per Cent. |
|---|---|---|
| Ash in coke | 9.09 × 1.5 = | 13.63 |
| Fixed carbon by difference | 100.00 − 13.63 = | 86.37 |
|  |  | 100.00 |
| Sulphur, separate | | .90 |

As the coking process, in the beehive oven at least, is by no means a perfect one, the analysis will be affected by the volatile matter in the coke due to imperfect burning and to the moisture resulting from watering down the charge. The sum of these should not exceed 2% in fairly good practice.

Either of the foregoing methods of estimating the yield and composition of coke give good results if the coal contains enough volatile matter to furnish the necessary heat for the coking process. It fails in the case of the semibituminous coals, as a certain amount of their fixed carbon is burned in supplying the heat for the coking operation. Using the analysis of Pocahontas coal, the theoretic yield of coke is, of course, the sum of the fixed carbon and ash or $73.87 + 5.25 = 79.12\%$, and its composition, using the first method given, should be, fixed carbon, $93.36\%$; ash, $6.64\%$; and sulphur (separately) .48%. But it is found that the yield in the beehive oven from coals of this type is commonly about 63% of the weight of the coal charged. Because all the ash remains in the coke and the fixed carbon alone is consumed, using a ton of 2,000 lb. as a basis, the composition of the coke is as follows:

2,000 lb. of coal yields $2,000 \times .6300 = 1,260$ lb.; fixed carbon + ash
2,000 lb. of coal yields $2,000 \times .0525 = 105$ lb.; ash
2,000 lb. of coal yields $1,260 - 105 = 1,155$ lb.; fixed carbon

Hence, 2,000 lb. of coal will yield 63%, or 1,260 lb., of coke, which contains 1,155 lb., or 91.67%, of fixed carbon and 105 lb., or 8.33%, of ash. The sulphur may be estimated to be from .64 as in the coal to .48% as determined by the first method.

If the coal is coked in a retort oven, the yield of coke will exceed the theoretic, and a fair average may be taken as 78% of the weight of the charge. Using the Connellsville coal mentioned, the yield and composition of coke in a retort oven will be about as follows:

2,000 lb. of coal yields $2,000 \times .7800 = 1,560$ lb.; fixed carbon + ash
2,000 lb. of coal yields $2,000 \times .0909 = 182$ lb.; ash
2,000 lb. of coal yields $1,560 - 182 = 1,378$ lb.; fixed carbon

Hence 2,000 lb. of coal will yield 78%, or 1,560 lb., of coke, which contains 1,378 lb., or 88.33%, of fixed carbon and 182 lb., or 11.67% of ash. It is apparent that coking in a retort oven gives more and better coke than coking in the beehive oven. The increased output is particularly noticeable in coking semibituminous coals.

Of the total coke produced in the beehive oven, between 95 and 96% will be of large size suitable for shipment to any market; 3 to 4% will be fine or small coke (breeze or braise) which may be separated from the ash by screening and sold for domestic use; and about 1% of ashes, which is usually worthless but is sometimes ground and used for foundry facings. The foregoing represents what may be called Connellsville practice; if semibituminous coal is used, the resultant coke is softer and the amount of fine coke and ashes is considerably greater.

**Pishel's Test for Coking Qualities of Coal.**—There has recently been developed, by Mr. Max. A. Pishel, a simple field test for determining the coking or non-coking properties of coals which should have extensive application. As described by Mr. Pishel in the columns of the *Colliery Engineer*, the procedure is: "Pulverize in a mortar a small quantity of the coal to be tested until it will pass through a 100-mesh sieve. Pour out the loose material and note the amount that adheres to the mortar. With some coals, the mortar and pestle will be deeply coated with coal dust that adheres so strongly that it can be removed with difficulty; with other coals, there will be only a thin film of coal dust adhering to the mortar and pestle; while with still others both mortar and pestle will be nearly as clean after the operation is completed as they were before it began. The degree of adhesion depends on the grade of the coal with reference to its coking qualities. If it adheres strongly, the coal will make a good coke; if it adheres only partly, the coal will make an inferior grade of coke; and if it does not adhere, the coal is non-coking." Porcelain, glass, earthenware, iron, or agate mortars may be used, the desideratum being that the material is hard and smooth. The results may be obtained as well with a small mortar that may be carried in the pocket as with a large one.

The structure of the coal in the bed affords some clue to its coking qualities; at least, it has been often noted that where the Pittsburg and Freeport seam coals, as well as those from the Pocahontas and New River districts, make a good coke, the coal shows a distinct columnar structure and tends to break out of the bed in long prisms or fingers.

**Non-Coking Coals.**—The term non-coking coals is applied to those bituminous coals that do not coke even when highly heated but which retain the shape of the original lump until reduced to ashes. There are numerous varieties known by distinctive names, and all are valuable domestic fuels.

**Fat and Dry, or Lean, Coals.**—Fat coals are those that possess a large amount of volatile matter and consequently burn with a long oily flame. Dry, or lean, coals are, obviously, the reverse of fat coals and burn with short flame and little smoke. Cannel coal affords an illustration of the first and Pocahontas of the second of these groups.

**Free-Burning Coal.**—The term free-burning is applied to those coals that burn easily with a light draft. The term is rather loosely used, being applied by some to non-coking coals, by others to semibituminous coals as opposed to anthracite, and by still others to coals containing a larger amount of volatile matter.

**Cannel Coal.**—Cannel coal is a variety of bituminous coal that is very rich in volatile matter, which makes it a very valuable gas coal. It kindles readily and burns with a dense smoky flame. It is compact, with little or no luster and without any appearance of banded structure, breaking with a conchoidal fracture. Its content of volatile is commonly about 50%, its color is dull black to grayish black, and its specific gravity is about 1.23. Certain varieties show what appear to be small concretions about the size of a dime scattered over the surface of a fresh fracture; these are called birds-eye cannel from the fancied resemblance of these structures. The name cannel coal is a corruption of the term *candle coal* given to it because long splints of it readily ignite and burn with a long flame, spitting and sputtering like a candle burning in a draft. It was at one time a popular grate fuel but, although extensive deposits exist, is now little mined.

**Splint Coal.**—Splint coal has a dull black color, and is much harder and less breakable than ordinary bituminous coal. It is readily fissile, like slate, but breaks with difficulty on cross-fracture. It ignites less readily than ordinary bituminous coal, but makes a hot fire, and is a good house coal, although its content of ash is usually high. Both it and cannel coal, while occurring in distinct seams, are very commonly found as a layer or layers interstratified in seams of ordinary coal.

## PROXIMATE ANALYSIS OF COAL

The following is the outline of the method recommended for the proximate analysis of coal by a committee of the American Chemical Society, Messrs. W. F. Hillebrand, C. B. Dudley, W. A. Noyes.

**Sampling.**—At least 5 lb. of coal should be taken for the original sample, with care to secure pieces that represent the average. These should be broken up and quartered down to obtain the smaller sample, which is to be reduced to a fine powder for analysis. The quartering and grinding should be carried out as rapidly as possible, and immediately after the original sample is taken, to prevent gain or loss of moisture. The powdered coal should be kept in a tightly stoppered tube, or bottle, until analyzed. Unless the coal contains less than 2% of moisture, the shipment of large samples in wooden boxes should be avoided.

In boiler tests, shovelfuls of coal should be taken at regular intervals and put in a tight covered barrel, or some air-tight covered receptacle, and the latter should be placed where it is protected from the heat of the furnace.

In sampling a mine, the map of the mine should be carefully examined and points for sampling located in such a manner as to represent fairly the body of the coal. These points should be placed close to the working face. Before sampling, a fresh cut of the face should be made from top to bottom to a depth that will insure the absence of possible changes or of sulphur and smoke from the blasting powders. The floor should be cleaned and a piece of canvas spread to catch the cuttings. Then, with a chisel, a cutting from floor to roof, say 3 in. wide and about 1 in. deep should be made. The shale or other impurities that it is the practice at that mine to reject should not be chiseled out, however. The length of the cutting made should then be measured, but the impurities should not be included in this measurement. With a piece of flat iron and a hammer, all pieces should be broken to ½-in. cubes or less, without removing from the cloth, then quartered, and transferred to a sealed bottle or jar. For the "run-of-mine" sample, samples taken at several points in this manner should be mixed and quartered down. If the vein varies in thickness at different points, the samples taken at each point should correspond in amount to the thickness of the vein. For instance, a

small measure may be filled as many times with the coal of the sample as the vein is feet in thickness. Should there appear differences in the nature of the coal, it will be more satisfactory to take, in addition to the general sample, samples of such portions of the vein as may display these differences.

**Moisture.**—Dry 1 g. of the coal in an open porcelain or platinum crucible at 104° to 107° C. for 1 hr., best in a double-walled bath containing pure toluene. Cool in a desiccator and weigh covered.

**Volatile Combustible Matter.**—Place 1 g. of fresh, undried coal in a platinum crucible weighing 20 to 30 g., and having a tightly fitting cover. Heat over the full flame of a Bunsen burner for 7 min. The crucible should be supported on a platinum triangle with the bottom 6 to 8 cm. above the top of the burner. The flame used should be fully 20 cm. high when burning free, and the determination made in a place free from drafts. The upper surface of the cover should burn clear but the under surface should remain covered with carbon. To find volatile combustible matter, subtract the percentage of moisture from the loss found here.

**Ash.**—Burn the portion of coal used for the determination of moisture at first over a very low flame, with the crucible open and inclined, until free from carbon. If properly treated, this sample can be burned much more quickly than the dense carbon left from the determination of volatile matter.

**Fixed Carbon.**—The fixed carbon is found by subtracting the percentage of ash from the percentage of coke.

**Sulphur (Eschka's Method).**—Mix thoroughly 1 g. of the finely powdered coal with 1 g. of magnesium oxide and $\frac{1}{2}$ g. of dry sodium carbonate, in a thin 75 to 100 c. c. platinum dish or crucible. The magnesium oxide should be light and porous, not a compact, heavy variety. Heat the dish on a triangle over an alcohol lamp, held in the hand at first; gas must not be used, because of the sulphur it contains. Stir the mixture frequently with a platinum wire and raise the heat very slowly, especially with soft coals. Keep the flame in motion and barely touching the dish, at first, until strong glowing has ceased, and then increase gradually until, in 15 min., the bottom of the dish is at a low red heat. When the carbon is burned, transfer the mass to a beaker and rinse the dish, using about 50 c. c. of water. Add 15 c. c. of saturated bromine water and boil for 5 min. Allow to settle, decant through a filter, boil a second and a third time with 30 c. c. of water, and wash until the filtrate gives only a slight opalescence with silver nitrate and nitric acid. The volume of the filtrate should be about 200 c. c. Add 1$\frac{1}{2}$ c. c. of concentrated hydrochloric acid, or a corresponding amount of dilute acid (8. c. c. of an acid of 8%). Boil until the bromine is expelled, and add to the hot solution, drop by drop, especially at first, and with constant stirring, 10 c. c. of a 10% solution of barium chloride. Digest on the water bath, or over a low flame, with occasional stirring until the precipitate settles clear quickly. Filter and wash, using either a Gooch crucible or a paper filter; the latter may be ignited moist in a platinum crucible, using a low flame until the carbon is burned.

In the case of coals containing much pyrites or calcium sulphate, the residue of magnesium oxide should be dissolved in hydrochloric acid and the solution tested for sulphuric acid.

When the sulphur in the coal is in the form of pyrites, that compound is converted almost entirely into ferric oxide in the determination of ash, and, as three atoms of oxygen replace four atoms of sulphur, the weight of the ash is less than the weight of the mineral matter in the coal by five-eighths the weight of the sulphur. While the error from this source is sometimes considerable, a correction for proximate analyses is not recommended. When analyses are to be used as a basis for calculating the heating effect of the coal, a correction should be made.

## FORMS OF REPORTING ANALYSES

The proximate analysis of a coal may be reported in one of several ways.

An analysis designated *as received* refers to the fact that the sample received no preliminary drying before analysis and usually represents the coal exactly as mined or as loaded on the railroad car, etc.

An analysis marked *as fired* refers to the fact that the sample for analysis was taken from the fuel in the boiler room, usually at the time of a test, and represents the coal as fired into the furnace.

An analysis denoted *air dried* refers to the fact that the sample was dried at a uniform temperature, usually the standard one of 62° F., for a number of hours before being analyzed.

In the first two cases, the moisture in the sample is commonly reported as moisture, or water, although the temperature at which the water is driven off is sometimes given. Thus, there are such expressions as "moisture at 212°," or "at 100°," "at 221°," or "at 105°," depending on the temperature and thermometric scale employed.

In the third case, the water is reported in two parts. The first, which represents the difference in the amount of water in the sample as received and after being dried in the laboratory at 62° F. is known as *air drying loss*, or as *loss on drying*. The second part represents the difference between the water in the air-dried sample and that given off on heating at 105° C. This is commonly reported as explained in connection with the first two cases, the temperature usually being stated.

An analysis reported *moisture free*, or as of *dry coal*, is one in which the sum of the percentages of fixed carbon, volatile matter, and ash equal 100. The moisture is reported as a separate item like the sulphur, and usually as, say, "moisture at 105° C."

An analysis reported as *dry and free from ash*, or as *ash and moisture free*, and even, although wrongly, as *pure coal*, is one in which the percentages of fixed carbon and volatile matter equal 100, the moisture and ash being reported separately.

Analyses reported in one form may readily be reduced to another. A proximate analysis made on a sample as received, as fired, or air-dried, may be reduced to a moisture-free basis by dividing each of the constituents, except the moisture, by 100 − moisture. If it is desired to reduce the analysis to a moisture- and ash-free basis, all the constituents except the moisture and ash, which are dropped, are divided by 100 − (moisture+ash). These divisors are applicable to the sulphur and calorific value (British thermal units) as well.

An ultimate analysis may, also, be reduced from the as received to the moisture free, or to the ash- and moisture-free basis by using the same divisors as before, provided the amount of moisture in the coal is known. The ash, sulphur, carbon, and nitrogen are divided in the regular way, but from the hydrogen must be deducted one-ninth of the moisture and from the oxygen, eight-ninths of the moisture.

### COAL 114 FROM SEWELL SEAM, McDONALD, W. VA.

| | | Air Dried | Divisor | Moisture Free | Divisor | Ash and Moisture Free |
|---|---|---|---|---|---|---|
| **Proximate Analysis** | Moisture............... | .68 | | 23.43 | | 24.71 |
| | Volatile matter......... | 23.28 | .9932 | 23.43 | .9418 | 24.71 |
| | Fixed carbon.......... | 70.91 | .9932 | 71.40 | .9418 | 75.29 |
| | Ash................... | 5.14 | .9932 | 5.17 | | |
| | Total............... | 100.00 | | 100.00 | | 100.00 |
| | Sulphur, separate...... | .91 | .9932 | .92 | .9418 | .97 |
| **Ultimate Analysis** | Carbon................ | 83.56 | .9932 | 84.13 | .9418 | 88.71 |
| | Hydrogen (−⅑ moisture)... | 4.66 | .9932 | 4.62 | .9418 | 4.86 |
| | Nitrogen.............. | 1.60 | .9932 | 1.61 | .9418 | 1.70 |
| | Oxygen (−⅛ moisture)..... | 4.13 | .9932 | 3.55 | .9418 | 3.74 |
| | Sulphur............... | .91 | .9932 | .92 | .9418 | .97 |
| | Ash.................. | 5.14 | .9932 | 5.17 | | |
| | Total.............. | 100.00 | | 100.00 | | 100.00 |
| | Calorific power........ | 14,765 | .9932 | 14,866 | .9418 | 15,680 |

The calculation shown in the table on page 380 is made upon a typical coal from the New River field, No. 114 of the table on pages 382 to 385, mined from the Sewell seam, at McDonald, W. Va. The second column contains both the proximate and the ultimate analyses and the calorific value, or power, in British thermal units per pound. The divisor in the third column is obtained by deducting the moisture from 100 and dividing by 100, or divisor $= (100 - .68) \div 100 = .9932$. By dividing all the figures in the second column by this divisor, those in the fourth column are obtained, and these represent the composition of the coal on a moisture-free, or dry-coal basis. The second divisor, that in the fifth column, is obtained by deducting the sum of the moisture and ash from 100 and dividing the result by 100, or divisor $= (100 - .68 - 5.14) \div 100 = .9418$. The figures in the second column (as before) excepting the ash and moisture if divided by this factor will give the figures in the sixth column, which represent the composition of the coal on an ash- and moisture-free, or on the dry-and-free-from-ash basis.

In dealing with the ultimate analysis, before applying either divisor, there must be deducted from the hydrogen and oxygen one-ninth and eight-ninths, respectively, of the moisture (.68) as given in the proximate analysis. The two dividends will be, respectively, $4.66 - (.68 \div 9) = 4.5844$, and $4.13 - (.68 \div 9) \times 8 = 3.5256$.

Should it be desired to give the percentage of moisture on a moisture-free basis, that is, as a separate determination similar to the sulphur, it may be obtained by dividing the moisture in the original sample by the factor in the third column, or moisture, separately determined $= .68 \div .9932 = .684$. If the moisture and ash are desired on the ash- and moisture-free basis, they may be had by dividing the percentage of these constituents in the second column by the divisor in the fifth column, and are, respectively, $.68 \div .9419 = .72$, and $5.14 \div .9419 = 5.45$.

## ANALYSES OF TYPICAL COALS

The table on pages 382 to 385 gives the proximate and the ultimate analyses and the calorific values, in British thermal units per pound, of a number of typical American coals, selected largely from the Reports of the Fuel Testing Plant at the St. Louis Exposition of 1904. Other anaylses are taken from various reports of the United States Geological Survey and the United States Bureau of Mines. Except as noted, all the analyses and heat determinations represent carload lots and were made on samples air-dried at the same temperature. For this reason, the relative values of the different coals are indicated by their calorific power as given in British thermal units. . The exceptions are: The proximate and the ultimate analyses and the heating values of coals 105, 110, and 111 were made upon samples marked "as received"; that is, the preliminary air-drying was omitted, and the analyses indicate more moisture and a lower calorific value in these coals than if they had been air-dried. Also, the ultimate analyses, but not the calorific values, of coals 15, 16, 17, 18, and 19, were made upon samples as received.

In the column headed Kind, A = anthracite; B = bituminous; B. L. = black lignite, the subbituminous coal of the United States Geological Survey; G. A. = graphitic anthracite; L = lignite, the true lignite or brown coal; P = peat; S. A. = semianthracite; S. B. = semibituminous.

In the column headed Grade, L = lump; N = nut; P = pea; R = run of mine; S = slack or culm. L. N. refers to a mixture of lump and nut; S. N. refers to a mixture of slack and nut; and, similarly, for other combinations of the letters.

In the proximate analyses, the sums of the moisture, volatile matter, fixed carbon, and ash should equal 100%. The sulphur is separately determined. In the ultimate analyses, the sums of the carbon, hydrogen, nitrogen, oxygen, sulphur, and ash should equal 100%.

In the table on page 386 is given a series of proximate analyses of Pennsylvania anthracite and semianthracite. Those marked C were made on samples of the coal as received or as fired, and represent a series of monthly or semimonthly shipments, usually extending over a year and in some cases aggregating 15,000 T. in weight. They were made with great care in order to determine the proper price to be paid for the coal, which was sold on analysis. The analyses marked D were made on air-dried samples previously collected in the mine by breaking down a full section of the working face. In all cases, regardless of the origin or preliminary treatment of the sample before analysis, the calorific values were determined on air-dried samples.

In the table on page 387, there is given a series of proximate analyses and calorific values of some important coals not contained in the table on pages

382 to 285. Those analyses marked C are of commercial lots delivered to the various government departments and represent the coal as received or, as fired. The analyses marked D were made from air-dried samples; in some cases they represent carload lots, and in others they are samples taken in the mine. The calorific values were determined upon air-dried samples except those given in *italics*, which were calculated from the analysis by means of Kent's formula. The analyses that are not marked with a C or a D are believed to represent air-dried samples, but those reporting them failed to state the facts in the case.

One of the accompanying tables gives a series of analyses of Alaskan coals taken from the reports of the United States Geological Survey. Among them are three analyses of coals from the Yukon Territory of Canada. The report does not state whether the analyses are of air-dried or as-received samples; judging from the amount of water in some specimens, it is presumed that they, at least, were of samples as received. The sulphur is separately determined.

A series of proximate analyses of foreign coals, many of which are used on the Pacific coast of the United States, is given in the table on page 387. The sample of coal from Argentine and the one from Rio Grande do Sul, Brazil, were tested at the United States Fuel Testing Plant, St. Louis, Missouri. They were treated in the same way as the samples of American coal given in the table on page 387. These two analyses are of air-dried samples and the heating values are 6,320 and 9,058 B. T. U., respectively. The heating value of the Victoria coal from Windmill shaft is given as 12,871 B. T. U. The other analyses are taken from various authorities, who fail to state whether they were made on air-dried or on as-received samples; judging from the small amount of water in most of them, the samples appear to have been air-dried before analysis. The sulphur is usually separately determined.

## PROXIMATE ANALYSES OF MISCELLANEOUS AMERICAN COALS

A series of proximate analyses and heating values of Canadian coals arranged by provinces, coal fields, mines, etc., is given in the table on pages 388 and 389. The analyses and heating-value determinations were made on samples dried at 212° F., consequently the sum of the volatile matter, fixed carbon, and ash equals 100. Both the moisture and sulphur were separately determined and do not enter in this total. By reason of the analyses, etc. being made on dry samples, the values in the table are higher than if made on air-dried samples and cannot be compared with those given in the table on pages 382 to 385. The samples were collected at the mine either at the working face or from coal being shipped and represent several tons in each case. The following abbreviations

## PROXIMATE ANALYSES OF ALASKAN COALS
### (*United States Geological Survey*)

| District and Kind of Coal | Mois-ture | Volatile Matter | Fixed Carbon | Ash | Sul-phur |
|---|---|---|---|---|---|
| Anthracite | | | | | |
| Bering River, average of seven analyses.................... | 7.88 | 6.15 | 78.23 | 7.74 | 1.30 |

## DETERMINATION OF HEATING VALUE OF COAL FROM A PROXIMATE ANALYSIS

A very good idea of the calorific power of a coal, from a commercial standpoint at least, may be obtained from a proximate analysis by some simple calculations. Of the two methods of doing this, that devised by William Kent and known by his name has a fairly general application. A method devised by Lord and Haas is restricted to a given field, but for the coals within that field it is probably more accurate than Kent's.

**Kent's Method.**—According to Kent, a relation exists between the amount of fixed carbon in the combustible portion of a coal (coal ash-and-moisture free, according to the fifth column in the calculation given under the head Proximate Analysis of Coal *ante*) and its calorific value per pound of combustible, which is shown in the following table.

These figures are correct within 2% for all coals containing more than 63% of fixed carbon in the combustible, but for coals containing less than 60% fixed carbon or more than 40% volatile matter in the combustible they are liable to an error, in either direction, of about 4%. The greater variation in the coals low in fixed carbon and high in volatile matter is due to the fact that they differ considerably in the percentage of oxygen in the volatile matter.

### APPROXIMATE HEATING VALUE OF COALS

| Per Cent. of Fixed Carbon in Coal Dry and Free From Ash | Heating Value per Pound Combustible | |
|---|---|---|
| | B. T. U. | Calories |
| 100 | 14,580 | 8,100 |
| 97 | 14,940 | 8,300 |
| 94 | 15,210 | 8,450 |
| 90 | 15,480 | 8,600 |
| 87 | 15,660 | 8,700 |
| 80 | 15,840 | 8,800 |
| 72 | 15,660 | 8,700 |
| 68 | 15,480 | 8,600 |
| 63 | 15,120 | 8,400 |
| 60 | 14,760 | 8,200 |
| 57 | 14,220 | 7,900 |
| 55 | 13,860 | 7,700 |
| 53 | 13,320 | 7,400 |
| 51 | 12,420 | 6,900 |

**Method of Lord and Haas.**—The following formula is based on extensive experiments made at the Ohio State University by Messrs. Lord and Haas and the results calculated by it have been found to agree very closely with those obtained with the Mahler calorimeter.

$$\text{B. T. U.} = \frac{K(100 - A - S - M) + (S \times 4,050)}{100} \quad (1)$$

in which the ash $A$, sulphur $S$, and moisture $M$ are expressed as percentages, and $K$ is a constant determined from a number of chemical and calorimetric determinations by the following formula, in which the values substituted are the averages of a number of analyses:

$$K = \frac{\text{B. T. U.} - (\text{sulphur} \times 4,050)}{100 - (\text{ash} + \text{sulphur} + \text{moisture})} \quad (2)$$

These gentlemen found that the value of $K$, which depends on the amount of moisture, ash, and sulphur in the coal, is practically constant for the same coal in the same field, regardless of any local variation in the relative proportions of these constituents. The value of $K$ as determined by them for various coals from Ohio, Pennsylvania, and West Virginia is given in the following table.

### VALUE OF $K$ FOR VARIOUS COALS

| Coal | Value of $K$ |
|---|---|
| Upper Freeport, Ohio and Pennsylvania................. | 15,116 |
| Pittsburg, Pennsylvania......................... | 15,183 |
| Middle Kittanning (Darlington coal), Pennsylvania........ | 15,062 |
| Middle Kittanning (Hocking Valley coal), Ohio............ | 14,265 |
| Thacker, West Virginia........................ | 15,410 |
| Pocahontas, West Virginia..................... | 15,829 |
| Fairmount, West Virginia..................... | 15,675 |

ILLUSTRATION 1.—*Lord and Haas' Method.*—Using coal No. 103 from Pocahontas, Va., as the sulphur is separately determined in the usual way, the percentages of ash and moisture must be recalculated, to what they would be if the sulphur were included. This is done by dividing them by $(100+S) \div 100 = 1.0074$, as the coal contains .74% of sulphur. From this the adjusted moisture and ash are, respectively, 1.62% and 5.82%. The value of $K$ to be used, 15,829, is taken from the table. Substituting in formula 1:

$$\text{B. T. U.} = \frac{15,829 \times (100 - 5.82 - .74 - 1.62) + (.74 \times 4,050)}{100} = 14,564$$

As the true calorific value is 14,672, the difference is 108 B. T. U., or .736%.
Kent's Method.—Using the same coal as before, No. 103, from the Pocahontas field in Virginia, the heating value of which has been determined by calorimeter to be 14,672 B. T. U. per lb., the proximate analysis is: Moisture, 1.63%; volatile matter, 17.17%; fixed carbon, 75.34%; and ash, 5.86%; the sum of these four constituents is 100%. The coal dry and free from ash is made up of $75.34 \div (75.34 + 17.17 = 92.51) = 81.44\%$ of fixed carbon, and $17.17 \div (75.34 + 17.17 = 92.51) = 18.56\%$ of volatile matter. By interpolating in the second column of the table, the heating value per pound of combustible of a coal dry and free from ash, and containing 81.44% of fixed carbon, is found to be 15,803 B. T. U. As just shown, the total combustible (the sum of the fixed carbon and volatile matter) in the coal is 92.51. Hence, the calorific value of this coal is $15,803 \times .9251 = 14,619$ B. T. U. This agrees very closely with the calorimetric value, the difference being but 48 B. T. U., or .361%.
ILLUSTRATION 2.—*Kent's Method.*—Using coal No. 78, of the table given on pages 382 to 385, from Henryetta, Okla., the heating value of which is 12,620 B. T. U., and which contains by analysis: Moisture, 3.87%; volatile matter, 35.73%; fixed carbon, 50.05%; and ash, **10.35%**. The fixed carbon in the coal dry and free from ash is 58.35% and the volatile matter is 41.65%. By interpolating in the second column of the table giving the approximate heating value of coals, the calorific value of a coal per pound of combustible and containing 58.35% of fixed carbon on a dry and ash-free basis, is 14,463 B. T. U. But the total combustible (fixed carbon+volatile matter) in this coal is $50.05 + 35.73 = 85.78\%$, hence its heating value is $14,463 \times .8578 = 12,406$ B. T. U. This differs from the true calorific value by 214 B. T. U., or 1.6%. It will be noted, however, that this coal contains less than 60% of fixed carbon, and is, thence, within the group in which the formula does not apply within 4%.
Lord and Haas' Method.—Taking the coal just used and recalculating the analysis to include the sulphur, the analysis is: Moisture, 3.80%; ash, 10.15%; and sulphur, 1.95%. The recalculated volatile matter is 35.03%, and fixed carbon 49.07%. This coal is not included in the table of those for which the value of $K$ has been determined. It is possible, however, for illustrative purposes only, to assume a value for this constant.
In content of volatile matter this coal is not unlike No. 82 from the Pittsburg seam, at Ellsworth, Pa., 35.73% as against 34.83%. Using the value of $K$, 15,183, for the Pittsburg seam, and substituting in formula 1, gives for the calorific value of this coal 12,848 B. T. U. per lb. This is 228 B. T. U., or **1.80%**, greater than the true value, 12,620 B. T. U.

In the amount of fixed carbon, 49.07%, this coal is not unlike No. 75, a Hocking coal from Dixie, Ohio, carrying 46.08% of fixed carbon. Using the value of $K$, 14,265, for Hocking coal, and substituting in the formula, gives the calorific value of coal No. 78 to be 12,076 B. T. U. This is 544 B. T. U., or 4.31% less than the true value.

The illustrations show that while this method gives excellent results with those coals for which the value of $K$ has been experimentally determined, it cannot be relied on to give good results where $K$ is unknown. Nor do Messrs. Lord and Haas make any such claim for it.

## DETERMINATION OF HEATING VALUE OF COAL FROM AN ULTIMATE ANALYSIS

**Dulong's Formula.**—The available method of determining the heating value of coal from an ultimate analysis is based on the formula devised by Dulong and known by his name. The amount of heat obtained in the burning of 1 lb. of coal under theoretically perfect conditions is expressed as follows:

$$\text{Lb. Cal.} = 8,080C + 34,462\left(H - \frac{O}{8}\right) + 2,250S$$

in which $C$, $H$, $O$, and $S$ are the percentages of the elements the symbols represent and the coefficients are the calories evolved in burning 1 lb. of carbon, hydrogen, and sulphur, respectively. The figures within the parenthesis $\left(H - \frac{O}{8}\right)$ represent the *available hydrogen*, i. e., the amount of that element over and above that required to combine with the oxygen to form water. American engineers commonly employ the British thermal unit in place of the pound-calorie. However, if calculations are made in pound-calories, they may readily be reduced to British thermal units by multiplying by 1.8.

In terms of the British thermal unit, the formula becomes,

$$\text{B. T. U.} = 14,544C + 62,032H + 4,050S$$

In this formula $C$, $H$, $O$, and $S$ are the percentages of carbon, hydrogen, oxygen, and sulphur, respectively, as determined by an ultimate analysis, and 14,544, 62,032, and 4,050, are the number of British thermal units evolved in burning 1 lb. of those of the foregoing elements that are combustible.

ILLUSTRATIONS.—Using coal No. 103 from Pocahontas, Va.,

$$\text{B. T. U.} = 14,544 \times .8314 + 62,032 \times \left(.0458 - \frac{.0465}{8}\right) + 4,050 \times .0075 = 14,603$$

This is within 69 B. T. U., or .470% of the calorimeter value.

In the case of coal No. 78, from Henryetta, Okla.,

$$\text{B. T. U.} = 14,544 \times .6985 + 62,028 \times \left(.0514 - \frac{.1138}{8}\right) + 4,050 \times .0199 = 12,547$$

which is 73 B. T. U., or .58%, too low.

Dulong's formula may be relied on to give results within 2% of the true calorimetrically determined value, and the agreement is generally much closer, as has been shown. It should be remembered that if the more accurate values for the calorific powers of the combustible elements are substituted in the formula, the results obtained are lower than those had through the use of the earlier and approximate ones.

A comparison of the results obtained in calculating the heating values of coals No. 103 and No. 78, by the different methods available is here given in tabular form.

| Method Employed | No. 103 B. T. U. | No. 78 B. T. U. |
|---|---|---|
| Actual value by calorimeter | 14,672 | 12,620 |
| Dulong's formula | 14,603 | 12,547 |

## PETROLEUM AS FUEL

Next to natural gas, petroleum is the ideal fuel, 1 lb. of it having a heating value about 50% greater than 1 lb. of average coal. Of the 209,556,048 bbl. produced in the United States in 1910, 24,586,108 bbl. were used for fuel by the railroads along the Pacific coast and in the Southwest, displacing, say, some 7,000,000 T. of coal. If to the consumption of the railroads is added that of steamships, central-station power plants, and other large industrial concerns, it is probable that the amount of oil used as fuel in the regions named is equivalent to about 20,000,000 T. of coal.

Petroleum is a dark greenish-black to light-brown oil produced by the decomposition of organic matter contained in the rocks, but whether the organic matter is of vegetable or animal origin is undetermined. The oil consists of a series of hydrocarbons that may be distilled off in a series of gradually increasing density as the temperature is increased. The residue, consisting of the least volatile portion, which commonly remains as a solid known as the *base*, affords a means of classifying oils into three groups: paraffin oils, asphalt oils, and olefin oils.

The oils in the first group are those produced in the eastern and middle western states and being limited in production and high in yield of very valuable light oils (gasoline, kerosene, etc.) are too high in cost to be used as fuel. In the second group come the oils of California and Texas, produced in large quantities and at low cost, and furnishing the vast bulk of the fuel oil used in the West and Southwest. In the third group are the oils of Baku, Russia, on the Caspian Sea, and, except in so far as they possibly displace American coal in foreign markets, are of no especial interest to the mining engineer.

**Composition of Crude Petroleum.**—Petroleum in the form in which it issues from the earth is known as *crude oil*. It usually contains from 83 to 87% of carbon; from 10 to 16% of hydrogen; and small amounts of oxygen, nitrogen, and sulphur. Crude oil contains from less than 1% to over 30% of water. The amount of water depends largely on the care with which the oil is pumped from the well. The oil from old producing wells commonly contains more water than that from wells newly drilled. In fact, in many districts, the percentage of water gradually increases during the life of the well, eventually the entire output being salt water. As the amount of water in the crude oil is uncertain and variable and as it separates out if left undisturbed, allowance must be made therefor in providing storage or, as more commonly called, *tankage*. The accompanying table gives the ultimate analyses of oils from various sources.

As stated, the various hydrocarbons composing crude petroleum may be separated by distillation at different temperatures; thus, gasoline is driven off by heating from 140° to 158° F.; a light benzine or naphtha at from 158° to 248° F.; heavier benzines at 248° to 347° F.; kerosene, or ordinary illuminating oil, at 338° F. and upwards; lubricating oils at 482° F. and above; paraffin wax at a higher temperature; leaving a tarry residuum that may be further distilled until nothing but a small quantity of coke remains in the still. If the distillation is stopped after the kerosene has been driven off, the residue may be used for fuel oil.

**Flash Point and Firing Point.**—If a sample of fuel oil or of crude oil is placed in an open cup and heat is applied, the oil will begin to vaporize and inflammable gases will be driven off. If, while the heating proceeds, a lighted match is passed at intervals over the surface of the oil and about ½ in. from it, a point will be reached at which the vapor rising from the oil will ignite and burn with a flicker of blue flame. The temperature of the oil when this flame first becomes apparent is termed the *flash point* of the oil. If the heating of the sample is continued, the vapors will be given off more rapidly and eventually they will ignite and burn continuously at the surface of the oil when the lighted match is brought near. The temperature of the oil when the burning becomes continuous is termed the *firing point* of the oil. The flash point and the firing point of an oil depend on the composition, specific gravity, and source of the oil. As a general rule, the heavier oils have a much higher flash point than the lighter ones and an attempt has been made to use this as a basis for classifying them. A specific gravity of .85 is taken as the basis, oils heavier than this having a flash point above 60° F., and oils lighter than this having a flash point lower than 60° F., although this is very far from always being true. It is obvious that a high flash point is very desirable in a fuel oil in order to avoid danger of explosion.

## ULTIMATE ANALYSES OF CRUDE PETROLEUM

| | Carbon | Hydrogen | Oxygen | Sulphur | Water | Specific Gravity | Flash Point Degrees | Calorific Power per Pound B. T. U. |

**Calorific Value of Fuel Oil.**—The combustible elements in oil are the same as those in coal, namely, carbon and hydrogen, and usually some sulphur. The calorific value per pound may be determined by means of Dulong's formula, which is applied exactly as in the case of an ultimate analysis of coal. This formula was used to calculate the greater number of the calorific powers given in the accompanying table. From the results of available tests, it is found that the heat of combustion per pound of fuel oil varies from 17,000 to 21,000 B. T. U., California oil averaging about 18,600 B. T. U., and Texas oil some 1,000 B. T. U. higher. At 18,600 B. T. U. per lb. and assuming an average specific gravity of .885, 1 gal. of oil weighs 7.37 lb., and will yield 137,082 B. T. U., and a barrel of 42 gal. will weigh 310 lb. and will yield 5,766,000 B. T. U. Using the same specific gravity and a calorific value of 19,600 B. T. U. per lb., 1 gal. of oil will develop 144,452 B. T. U., and a barrel 6,076,000 B. T. U. The theoretical comparative fuel values of coals of different heating powers

[1] Includes nitrogen.
[2] Oxygen, by difference.
[3] Calculated by means of Dulong's formula.

and of fuel oil yielding, respectively, 18,600 and 19,600 B. T. U., per lb. are given in the following table.

This table, however, is of more theoretical than practical interest, as it is based on the assumption that combustion is perfect whether oil or coal is used, and that, in consequence, the efficiency of an oil-burning and of a coal-burning boiler is the same. This is far from the case, as the efficiency of a properly designed oil-burning boiler is the greater. To this must be added the advantages outlined, so that only an actual test of the two fuels will determine which is the more economical under a given set of conditions.

## COMPARATIVE VALUE OF COAL AND OIL AS FUEL

| Thermal Value of Different Coals B. T. U. per Pound | At 18,600 B. T. U. per Lb. | | | At 19,600 B. T. U. per Lb. | | |
|---|---|---|---|---|---|---|
| | Pounds of Coal Equivalent to 1 Lb. of Petroleum | Pounds of Coal Equivalent to 1 Bbl. of Petroleum | Barrels of Petroleum Equivalent to 1 T. of Coal | Pounds of Coal Equivalent to 1 Lb. of Petroleum | Pounds of Coal Equivalent to 1 Bbl. of Petroleum | Barrels of Petroleum Equivalent to 1 T. of Coal |
| 10,000 | 1.860 | 577 | 3.47 | 1.960 | 608 | 3.29 |
| 11,000 | 1.691 | 524 | 3.82 | 1.782 | 552 | 3.62 |
| 12,000 | 1.550 | 481 | 4.16 | 1.633 | 506 | 3.95 |
| 13,000 | 1.431 | 444 | 4.51 | 1.508 | 467 | 4.28 |
| 14,000 | 1.329 | 412 | 4.85 | 1.400 | 434 | 4.61 |
| 15,000 | 1.240 | 384 | 5.21 | 1.307 | 405 | 4.95 |

**Advantages and Disadvantages of Oil Fuel.**—Babcock and Wilcox summarize the advantages of fuel oil as follows:

1. The cost of handling is much lower, the oil being fed by simple mechanical means, resulting in

2. A general labor saving throughout the plant in the elimination of stokers, coal passers, ash handlers, etc.

3. For equal heat value, oil occupies very much less space than coal. This storage space may be at any distance from the boiler without detriment.

4. Higher efficiencies and capacities are obtainable with oil than with coal. The combustion is more perfect as the excess air is reduced to a minimum; the furnace temperature may be kept practically constant, as the furnace doors need not be opened for cleaning or working fires; smoke may be eliminated with the consequent increased cleanliness of the heating surfaces.

5. The intensity of the fire can be almost instantaneously regulated to meet load fluctuations.

6. Oil, when stored, does not lose in calorific value as does coal, nor are there any difficulties arising from disintegration, such as may be found where coal is stored.

7. Cleanliness and freedom from dust and ashes in the boiler room with a consequent saving in wear and tear on machinery; little or no damage to surrounding property due to such dust.

The disadvantages of oil are:

1. The necessity that the oil have a reasonably high flash point to minimize the danger of explosions.

2. City or town ordinances may impose burdensome conditions relative to location and isolation of storage tanks, which in the case of a plant situated in a congested portion of the city, might make the use of this fuel prohibitive.

3. Unless the boilers and furnaces are especially adapted for the use of this fuel, the boiler upkeep cost will be higher than if coal is used.

The relative cost of the two fuels per unit of power produced is, of course, the deciding factor in the premises, and this varies so greatly in such short intervals of time, even from day to day, that current quotations of the delivered cost of both fuels must always be used in making calculations of the savings possible when substituting oil for coal, and vice versa.

## GASEOUS FUELS

**Kinds of Gas.**—The different gases used as fuel are the following, arranged in the order of their heating value: (1) *Natural gas*, which is obtained from wells in different parts of the world; (2) *illuminating gas*, or *coal gas*, which is made either by distilling coal in retorts or by enriching water gas with the volatile matter distilled from cannel coal or with vapors distilled from petroleum; (3) *coke-oven gases*, which are mainly those coming from by-product ovens, although occasionally the gases from the beehive ovens are used under boilers; (4) *water gas*, which is made by blowing steam through a bed of glowing anthracite or coke, by the reaction $C + H_2O = CO + 2H$; (5) *producer gas*, which is made by blowing air into burning bituminous coal, in which case the volatile matter, including condensible tarry vapors, is distilled, and the coke is burned to carbon monoxide; producer gas is also made by blowing air into burning anthracite, thus producing carbon monoxide; (6) *combined water gas* and *producer gas*, which is made by blowing air mixed with steam into a producer charged with burning bituminous coal; (7) *blast-furnace gas*, which is the waste gas coming from the top of a blast furnace, and which contains a certain amount of carbon monoxide available as fuel.

The composition and heating value of different gases, as given by H. A. Humphrey in the Proceedings of the Institution of Civil Engineers of Great Britain, are shown in the following table.

### ANALYSES AND HEATING VALUES OF VARIOUS GASES

| Constituent Gases | Pittsburg Natural Gas Volume Per Cent. | Coal Gas (Illuminating) Volume Per Cent. | Solvay Coke-Oven Gas Volume Per Cent. | Lencanchez Producer Gas From Anthracite Volume Per Cent. | Dowson Producer Gas From Anthracite Volume Per Cent. | Siemen's Producer Gas From Bituminous Coal Volume Per Cent. | Mond Producer Gas From Bituminous Coal Volume Per Cent. |
|---|---|---|---|---|---|---|---|
| Hydrogen, $H$ | 22.0 | 48.0 | 56.9 | 20.0 | 18.7 | 8.6 | 24.8 |
| Marsh gas (methane), $CH_4$ | 67.0 | 39.5 | 22.6 | | .3 | 2.4 | 2.3 |
| $C_nH_{2n}$ gases | 6.0 | 3.8 | 3.0 | 4.0 | .3 | | |
| Carbon monoxide, $CO$ | .6 | 7.5 | 8.7 | 21.0 | 25.1 | 24.4 | 13.2 |
| Carbon dioxide, $CO_2$ | .6 | | 3.0 | 5.0 | 6.6 | 5.2 | 12.9 |
| Nitrogen, $N$ | 3.0 | .5 | 5.8 | 49.5 | 49.0 | 59.4 | 46.8 |
| Total volume (approximate) | 100.0 | 100.0 | 100.0 | 100.0 | 100.0 | 100.0 | 100.0 |
| Total combustible gases | 95.6 | 98.8 | 91.2 | 45.0 | 44.4 | 35.4 | 40.3 |
| Heating value (B. T. U. per cubic foot at 64° F.) | 892.4 | 686.0 | 511.0 | 207.5 | 160.0 | 134.5 | 154.6 |

Some additional analyses of natural, producer, and coke-oven gases, together with their average heating values, are given in another table.

The heating value per pound and per cubic foot, measured at 32° F., and atmospheric pressure of the several constituents of a mixed fuel are given in the table on page 400. The figures in the first column are those of Favre and Silbermann except in the two cases noted. Other heating values differing slightly from these are given by different authorities, owing to a difference in the experiments by which the values have been determined. In the third column are shown approximate figures, giving the British thermal units per pound of combustible, that are within the limits of error of chemical analysis.

**Blast-Furnace Gases.**—Blast-furnace gas varies greatly in its composition, and in six analyses made in 1 da., the carbon dioxide varied from 6.6 to 7.7%, the carbon monoxide from 20.1 to 31.7%, and the nitrogen and hydrocarbons

## ANALYSES OF NATURAL, PRODUCER, AND COKE-OVEN GASES

| Sulphur to $SO_2$.......................... | 4,050† | | 4,000 |

from 60.5 to 72.2% by volume. The heating value calculated from the average analyses was 1,175 B. T. U. per lb., and at the temperature of 584° F., at which it entered the steam boiler furnace, it carried 140 B. T. U. per lb. additional heat. The 1,175 B. T. U. per lb. are equal to about 94 B. T. U. per cu. ft., measured at 32° F., or only about one-tenth of the value of 1 cu. ft. of natural gas.

Modern blast furnaces, working on Bessemer iron, will produce about 8,500 lb. of available gas per ton of pig iron made. This gas will have an average composition of about $CO_2$, 10.80%; $CO$, 28.00%; $H$, 2.50%; $CH_4$, .2%; and $N$, 58.50%; and will yield 85 to 100 B. T. U. per cu. ft., or 1,050 to 1,250 B. T. U. per lb., assuming that the weight of 1 cu. ft. thereof is .081 lb. The heat from the waste gases of the blast furnaces in the United States, which produced about 26,700,000 T. of pig iron in 1910, was sufficient, if entirely utilized, to have displaced 10,400,000 T. of coal having a fuel value of 12,000 B. T. U. per lb.

**Natural Gas.**—Natural gas, produced from drilled wells, usually in or near the oil fields, is a valuable fuel in many states. The total production in 1910 was 509,155,309,000,000 cu. ft. The value is placed at $70,756,158, or 13.90 c. per 1,000 cu. ft., varying from 7.16 c. per cu. ft. in West Virginia to 73.77 c. in South Dakota. Assuming a fuel value of 1,000 B. T. U. per cu. ft., this gas displaced 21,000,000 T. of coal rated at 12,000 B. T. U. per lb. The 1,327,722 domestic consumers used 169,823,030,000,000 cu. ft. of gas, for which they paid an average price of 24.4 c. per 1,000 cu. ft., the rate charged varyingf rom 16.9 c. per 1,000 ft. in Oklahoma to $1 in Michigan. The 18,267 industrial establishments used 339,332,279,000,000 cu. ft., for which they paid an average price of 8.63 c. per 1,000 cu. ft., the rate charged varying from 5.1 c. per 1,000 cu. ft. in West Virginia to 69.5 c. in South Dakota.

The great variation in the composition of natural gas from different fields is shown in the table on page 399. Assuming a calorific value of 1,000 B. T. U. per cu. ft., 24,000 cu. ft. of gas will yield as much heat as 1 T. of coal rated at 12,000 B. T. U. per lb. To displace 1 T. of high-grade Pocahontas or New River coal rated at, say, 14,750 B. T. U. per lb., will require 29,500 cu. ft. of gas. The number of cubic feet of gas required to displace 1 T. of coal when the calorific powers of each are known, may be found by dividing twice the calorific power of the coal per pound by the ratio the calorific power of the gas bears to 1,000 B. T. U.

EXAMPLE.—(a) How many thousand cubic feet of gas having a calorific power of 925 B. T. U. per cu. ft., will be required to displace 1 T. of coal rated at 13,965 B. T. U. per lb.? (b) How many cubic feet will be required if the heating value of the gas is 1,155 B. T. U. per lb.?

*Calculated. †N. W. Lord.

SOLUTION.—(a) It is assumed that the efficiency of the boiler is the same regardless of the fuel used. $\frac{13,965 \times 2}{.925} = 30,195$ cu. ft.

(b) $\frac{13,965 \times 2}{1.155} = 24,181$ cu. ft.

It is possible, also, to deduce from this that 1,000 cu. ft. of the first gas $= 2,000 \div 30.195 = 66.23$ lb. of the coal, and 1,000 cu. ft. of the second gas $= 2,000 \div 24.181 = 82.71$ lb. of the coal. Likewise, 1 lb. of the coal is equal to $1,000 \div 66.23 = 15.09$ cu. ft. of the first gas, and is equal to $1,000 \div 82.71 = 12.10$ cu. ft. of the second gas.

In the matter of natural gas in the Pittsburg, Pa., district, a committee of the Western Society of Engineers report that 1 lb. of good coal is equal to $7\frac{1}{2}$ cu. ft. of natural gas. When burned with just enough air, its temperature of combustion is 4.200° F. The Westinghouse Air Brake Company found from experiment that 1 lb. of Youghiogheny coal is equal $12\frac{1}{4}$ cu. ft. of natural gas, or 1,000 cu. ft. of natural gas is equal 81.6 lb. of coal. Indiana natural gas gives 1,000,000 B. T. U. per 1,000 cu. ft., and weighs .045 lb. per cu. ft.

Natural gas, when used for steam raising, is commonly under a pressure of about 8 oz. and is fired through a large number of small burners to prevent what is known as *lancing*, or the issuing of the flame in a long jet similar in appearance and largely in action to that of a blow-pipe.

**By-Product Gas.**—By-product gas, so called, is given off in large amount in connection with the numerous by-product processes of coking. When the coking plant is situated at a steel works, the gas is used for the generation of steam; if situated in or near a city, the gas is enriched and used for illuminating and general fuel purposes, as is done at the plant of the New England Gas and Coke Company at Everett, near Boston, Mass.

In 1910 there were 4,078 by-product ovens in the United States, of which all but 27 were in blast. They consumed 9,529,042 T. of coal and produced 7,138,734 T. of coke, an average yield of 74.9%. A certain amount of the gas given off by the coking coal is required to furnish the heat demanded by the process; the gas not so used, the surplus or available gas, amounted, in 1910, to 27,692,858,000 cu. ft., valued at \$3,017,908, or about 11 c. per 1,000 cu. ft. The production appears to be, from these statistics, at the rate of 2,900 cu. ft. per T. of coal charged, or 3,880 cu. ft. per T. of coke drawn. These figures are approximate and to be used with caution because at a small number of plants no attempt was made to save the gas, and at another, the yield of gas had to be estimated.

The amount of gas available depends on so many factors that it is impossible to predicate just how much and what grade of gas a given coal will yield. Obviously, the amount of gas available from coking 1 T. of high-volatile Connellsville coal is much greater than that to be had from a lean semibituminous coal. The composition of the gas will vary with the composition of the coal and with the process employed in coking. The gas will also depend, in a very great measure, on whether the ovens are designed primarily for coke making, as at a steel or iron plant, or whether intended for the manufacture of illuminating gas and the recovery of by-products (in this case, the coke being a by-product), as at Everett, near Boston.

In regard to the yield of gas per ton of coal charged, the 280 Koppers regenerative ovens at Joliet, Ill., when charged with a mixture of 80% Pocahontas and 20% high-volatile coal, yielded 84% of the coal charged as coke and 10,000 cu. ft. of gas per T., of which rather more than 5,000 cu. ft. was surplus and available as fuel. The same oven, operating in Germany on a coal not dissimilar to the Connellsville, Pa., yields between 5,000 and 6,000 cu. ft. of available gas per T. Mr. F. E. Lucas, superintendent of the coke-oven department of the Dominion Iron and Steel Co., Sydney, N. S., estimates the average yield of surplus gas from average coal in by-product ovens as 5,000 cu. ft. per T. of coal charged, and that this gas has a fuel value of from 450 to 500 B. T. U. per cu. ft. At Mulheim-on-the-Ruhr, Germany, a plant of 50 Koppers ovens supplies that city and Barmen, 40 mi. distant, with gas; these ovens take 8 to 10 T. of coal at a charge. The time of coking is 24 hr. but only the richer portion of the gas, that evolved from the second to the twelfth hour, which is about 50% of the yield, is distributed. During these 10 hr., each oven produces 70,600 cu. ft. of gas of a calorific value well over 600 B. T. U. per cu. ft., with the average composition: $CO_2$, 1.2%; $CO$, 6.8%; $H$, 49.5%; $CH_4$, 38.3%; and $N$, 4.2%. Mr. Edwin A. Moore, estimates that a plant of 100 United-Otto ovens consuming 750 T. of coal will produce 3,472,000 cu. ft.

of available gas, or at the rate of 4,630 cu. ft. of gas per T. of coal charged. Mr. Moore calls attention to the fact that the gases given off during the early portion of the coking process (first 10 hr.) have a fuel value of 650 B. T. U. per cu. ft., and during the latter period, but 525 B. T. U.  It would appear that the average coal will yield about 4,500 cu. ft. of available gas per T., and that the gas has a heating value of some 500 B. T. U. per cu. ft.; on which basis the gas has about 8.5% of the heating value of the coal from which it is made, assuming the latter to be rated at around 13,000 B. T. U. per lb.

On the basis of containing 500 B. T. U. per cu. ft., the 27,692,858,000 cu. ft. of by-product gas marketed in 1910 displaced about 580,000 T. of coal with a fuel value of 12,000 B. T. U. per lb.

As this gas is highly charged with moisture, arrangements must be made for getting rid of the condensed water.  Further, as the gas carries large amounts of tar and heavy hydrocarbons that clog the burners, arrangements must be made whereby they may be cleaned out by blowing steam through them.

**Coke-Oven Gas.**—Beehive coke-oven gases are used at numerous mines for the generation of the necessary steam for operating the power plant connected therewith.  As these gases do not contain any combustible portion, their value lies in their sensible heat.  The total horsepower available may be obtained from the formula, 

$$HP = \frac{W(T-t)s}{33,000}$$

in which

$W$ = weight of gases passing per hour;
$T$ = temperature of gases entering boiler;
$t$ = temperature of gases leaving boiler;
$s$ = specific heat of gases.

As the temperature of the gases entering the boiler is rarely as great as 2,000° F., and as with coal firing the furnace temperature ranges from 2,500° to 3,000°, the heating surface first passed over will not absorb as much heat in the waste-heat boilers, and, consequently, the heating surface per boiler horsepower should be increased.  From 12 to 15 ft. in water-tube boilers is about right, and from 15 to 20 ft. in return tubular and shell boilers.

In a series of tests with a high-class water-tube boiler, the following results were obtained with the waste heat from the coke ovens:  Temperature of the gases entering the boiler, 1,720° F.; temperature of gases leaving the boiler, 650° F.; boiler heating surface, 1,611 sq. ft.; water evaporated per hour from and at 212° F., 6,465 lb.; water evaporated from and at 212° per oven per hour, 294 lb.; water evaporated from and at 212° per lb. of coal coked, 1.7 lb.; water evaporated from and at 212° per sq. ft. of heating surface, 4 lb.

At the Sydney Mines of the Nova Scotia Steel and Coal Company, the waste heat from coke ovens of the Bauer type is used in the generation of steam.  In referring to a test run made upon a single boiler, Mr. Thomas J. Brown, the superintendent, obtained these results:  Average horsepower per hour, 331; maximum horsepower per hour, 436; minimum horsepower per hour, 179; evaporation from and at 212° per lb. of coal charged into the ovens, 1.18 lb. of water; coal charged into the ovens per boiler horsepower, 29.23 lb. Mr. Brown further states, that the boilers have 3,140 sq. ft. of heating surface, with a flue temperature at the rear of the boilers of between 600° and 700°, and that the proportion of about 9.5 sq. ft. of heating surface per horsepower developed seems to be about right for this class of fuel.

At Marianna, Pa., 2,000 H. P. are developed from a battery of 75 beehive ovens at a cost of $2.50 per da. as opposed to a cost of $63.50 if coal were used. At the Stag Cañon Mines, Dawson, N. Mex., 2,400 H. P. are developed from the waste gases of 218 beehive ovens, the gases being delivered under the boilers at temperatures ranging from 1,800° F. to 2,600° F. and leaving the stack at from 600° to 1,150° F.  Mr. R. D. Martin, referring to the waste heat ovens in use at Agujita and Lampacitos, Coahuila, Mex., estimates that each coke oven is capable of developing 12 boiler H. P. from a coal containing, volatile matter, 21.1%; fixed carbon, 67.4%; and ash, 11.5%.  Here the temperature in the firebox, as determined with Saeger cones, was as high as 2,600° F. Mr. Howard N. Eavenson, in connection with the Continental Coke Co., No. 1 plant, estimates that the waste heat from 6 T. of coal charged into a coke oven will yield as many boiler horsepower as 1 T. of coal directly fired.

**Coal Gas.**—Coal gas, frequently called *illuminating gas* from the use to which it is ordinarily put, is made by heating bituminous coal high in volatile matter in fireclay retorts of a semielliptic cross-section.  The retorts are about

15 in. high by 26 in. wide inside, and 9 to 10 ft. long if single-ended, or 18 to 20 ft. long if double-ended. The retort walls are about 4 in. thick and each retort is connected with a pipe that allows the gases to escape as fast as formed. After passing through various devices to remove the ammonia, tar, and sulphur, the gas passes into a gas holder and is ready for distribution.

Analyses of typical gas coals from the Pittsburg, Pa., field are given in the following table.

## ANALYSES OF GAS COALS

| Constituents | Westmoreland Coal Company | | | Pennsylvania Gas Coal Company | | |
|---|---|---|---|---|---|---|
| | South Side Mine | Foster Mine | Larri- mer No. 2 | Irwin No. 1 | Irwin | Sewick- ley |
| Water............. | 1.410 | 1.310 | 1.560 | 1.78 | 1.280 | 1.490 |
| Volatile matter.... | 37.655 | 37.100 | 39.185 | 35.36 | 38.105 | 37.153 |
| Fixed carbon...... | 54.439 | 55.004 | 54.352 | 59.29 | 54.383 | 58.193 |
| Sulphur............ | .636 | .636 | .643 | .68 | .792 | .658 |
| Ash............... | 5.860 | 5.950 | 5.950 | 2.89 | 5.440 | 2.506 |
| Total......... | 100.000 | 100.000 | 100.000 | 100.00 | 100.000 | 100.000 |

Under ordinary conditions 1 T. of such coal should produce about 10,000 cu. ft. of gas of 17 c. p., 1,400 lb. of coke, 12 gal. of tar, and 4 lb. of ammonia.

The following may be considered as the average composition of purified coal gas:

|  | *Per Cent.* |
|---|---|
| Hydrocarbon vapors.............................. | .6 |
| Heavy hydrocarbons............................. | 4.4 |
| Carbon dioxide, $CO_2$.............................. | 3.4 |
| Carbon monoxide, $CO$............................ | 10.1 |
| Marsh gas, $CH_4$................................. | 30.6 |
| Oxygen, $O$..................................... | .3 |
| Hydrogen, $H$................................... | 45.9 |
| Nitrogen, $N$................................... | 4.7 |
| Total......................................... | 100.0 |

The use of illuminating gas as fuel for steam-raising is limited by its cost which, while sometimes as low as 80 c. per 1,000 cu. ft., is usually about $1. A certain amount is used directly in small gas engines in the larger cities, but the larger amount is used for illumination or in cooking ranges, domestic heating stoves, and the like. Coal gas made from gas coals in retorts is being largely displaced by water gas.

**Water Gas.**—Water gas contains the same combustible constituents as coal gas but not in the same proportions. It is made commercially by the contact of steam with incandescent carbon, in the form of anthracite or coke, which decomposes the steam separating the hydrogen from the oxygen. The oxygen takes up carbon from the coal or coke and forms carbon monoxide, along with a small amount of carbon dioxide. The resultant gases therefore are mainly hydrogen and carbon monoxide mechanically mixed together. This is what is called *blue*, or *uncarbureted, water gas*. It burns with a non-luminous flame and is consequently useless for lighting purposes, except in incandescent lamps of the Welsbach type. In actual practice, this water gas is always enriched with oil gas, which furnishes the hydrocarbons necessary to make a luminous flame. The oil gas was made separately in many of the older forms of apparatus, but it is now commonly produced in the same apparatus in which the water gas is made.

The only impurity that must be removed from water gas is hydrogen sulphide, which is formed from the sulphur that is always present in varying amounts in the coal or coke and sometimes in the oil. The hydrogen sulphide

is removed by purification with lime or iron oxide in the same way that the purification of coal gas is accomplished.

Carbon dioxide, which is formed either by imperfect contact of the steam with the incandescent carbon, or because the temperature of the carbon is too low, is not a dangerous impurity, but is merely an inert gas incapable of combustion. It, however, absorbs heat when the gas is burned, and is consequently injurious to the heating and lighting power. It can be removed by purification with lime, but this is not necessary if the generating apparatus is handled properly, as the quantity made will be very small. No ammonia is produced.

The following is a volumetric analysis of purified water gas:

|  | Per Cent. |
|---|---|
| Hydrocarbon vapors | 1.2 |
| Heavy hydrocarbons | 12.6 |
| Carbon dioxide, $CO_2$ | 3.0 |
| Carbon monoxide, $CO$ | 28.0 |
| Marsh gas, $CH_4$ | 20.2 |
| Oxygen, $O$ | .4 |
| Hydrogen, $H$ | 31.4 |
| Nitrogen, $N$ | 3.2 |
| Total | 100.0 |

Water gas requires from 30 to 40 lb. of coal or coke per 1,000 cu. ft. of gas made, and from 4 to 5 gal. of oil, depending on the candlepower required. Usually between 5 and 6 c. p. is obtained from each gallon of oil used. The specific gravity of 24 c. p. water gas is about .625, air being taken as unity.

Pure uncarbureted water gas has no perceptible odor, but the carbureted gas has an odor fully as strong as coal gas. This is mainly due to the hydrocarbons from the oil that is used for enriching. It should be noted that these hydrocarbons are not added if the gas is to be used for heating or in gas engines.

**Producer Gas.**—Producer gas is made in a cylindrical riveted shell of boiler plate, lined with firebrick. A thick bed of fuel is maintained in the bottom of the producer and through this is passed a moderate supply of air, with or without water vapor or steam. By properly regulating the air supply, a partial or incomplete combustion of the fuel is maintained, resulting in the gradual consumption of all the combustible matter. The coke, instead of remaining as a by-product, as in the manufacture of coal gas or in by-product or retort coke ovens, is all consumed in making the gas. When dry air alone is forced through the fire, the resulting gas is known as *air gas* and is the true producer gas; when the air is mixed with steam or water vapor the resulting gas is called *mixed gas*, and is frequently made in producers; and when air is not used at all and steam alone is forced through the fire, the product is called water gas as previously explained.

The quantity of producer gas derivable from 1 T. of fuel will vary according to the fuel used, the type of producer plant, and the method of operating. The United States Geological Survey, at its Fuel Testing Plant at the Louisiana Purchase Exposition, held in St. Louis, in 1904, made an exhaustive series of tests of American coals used in gas producers, and from its reports the following tables, etc., are taken.

### QUANTITY OF GAS PRODUCED PER POUND OF FUEL IN AN UP-DRAFT PRESSURE PRODUCER

| Fuel | Maximum | | Minimum | | Average | |
|---|---|---|---|---|---|---|
| | As Fired Cubic Feet | Dry Cubic Feet | As Fired Cubic Feet | Dry Cubic Feet | As Fired Cubic Feet | Dry Cubic Feet |
| Bituminous coal | 100.8 | 100.3 | 37.0 | 40.9 | 60.5 | 64.7 |
| Lignite | 45.9 | 52.8 | 26.1 | 38.8 | 35.8 | 45.7 |
| Peat | | | | | 30.3 | 38.3 |

The yield of gas, in cubic feet per pound of dry fuel, which may be expected in the up-draft producer from various fuels is, roughly, as follows: Coke or charcoal, 90; anthracite, 75; bituminous coal, 65; lignite, 46; and peat, 38. On the basis of the Survey's tests the yield of gas and the heat value of the gas per ton of fuel as fired are approximately as in the table here given.

**YIELD AND HEAT VALUE OF GAS PER TON OF FUEL AS FIRED IN AN UP-DRAFT PRESSURE PRODUCER**

| Kind of Fuel | Cubic Feet of Gas per Ton of Fuel as Fired | British Thermal Units in Gas, per Cubic Foot | British Thermal Units in Gas, per Ton of Fuel as Fired |
|---|---|---|---|
| Coke or charcoal........... | 170,000 | 140 | 23,800,000 |
| Anthracite................ | 140,000 | 135 | 19,000,000 |
| Bituminous coal........... | 120,000 | 152 | 18,300,000 |
| Lignite................... | 72,000 | 158 | 11,400,000 |
| Peat...................... | 60,000 | 175 | 10,000,000 |

It will be noted from this table that while the inferior fuels yield less gas per ton, as might be expected, the heating value of the gas, in British thermal units per cubic foot, is greater than in gas made from high-class coals.

**Gas Producers.**—There are three general types of gas producer in use. In the *suction* type, the drawing of the air and steam through the fire and, consequently, the generation of the gas, is accomplished by the suction in the engine cylinder in which the gas is used. While the gases are scrubbed, etc., to get rid of the tar that otherwise would clog the cylinders, the absence of storage tanks for the gas and the fact that the suction of the engine causes the operation of the producer, renders absolute separation of the tar difficult if not impossible. Hence, only low volatile coals are adapted to use in this type of producer, and because the price of such coals is always high, suction plants, though numerous, are of comparatively small power, few exceeding 300 H. P. each, and most of them not exceeding 100 H. P.

The *up-draft pressure producer* is the common American type in which the gas is developed under a slight pressure due to the introduction of the air and steam blasts, and the gas is stored in holders until required by the engine. As the generation of the gas is independent of the suction stroke of the engine, tar and other impurities may be removed by suitable devices and hence the use of bituminous coal, lignite, and peat is possible. This form of producer is offered in many types, some of which are without gas holders and are proving eminently satisfactory. If the holder is omitted, automatic devices must be introduced for controlling the pressure and the supply of gas to the engine.

**TYPICAL ANALYSES BY VOLUME OF PRODUCER GAS**

| | From Bituminous Coal Per Cent. | | From Lignite Per Cent. | | From Peat Per Cent. | |
|---|---|---|---|---|---|---|
| | U. D. | D. D. | U. D. | D. D. | U. D. | D. D. |
| Carbon dioxide, $CO_2$....... | 9.84 | 6.22 | 10.55 | 11.87 | 12.40 | 10.94 |
| Oxygen, $O_2$............... | .04 | .13 | .16 | .01 | | .41 |
| Ethylene, $C_2H_4$........... | .18 | .01 | .17 | | .40 | .06 |
| Carbon monoxide, $CO$.... | 18.28 | 21.05 | 18.72 | 16.01 | 21.00 | 16.91 |
| Hydrogen, $H_2$............. | 12.90 | 12.01 | 13.74 | 14.66 | 18.50 | 10.19 |
| Methane, $CH_4$............. | 3.12 | .49 | 3.44 | .98 | 2.20 | .66 |
| Nitrogen, $N_2$............. | 55.64 | 60.09 | 53.22 | 56.37 | 45.50 | 60.83 |

In both the foregoing types of producer, the extraction of the tar removes a large part of the heat value of the gas. If the tar can be sold at a good price this may not make much difference, but where the tar is thrown away the loss is sufficient to warrant the attempt to devise some means of converting this tar into gas of suitable quality for engine use. To this end *down-draft producers* are coming into general use and in them the gases are drawn down through the bed of coal and the tar is thereby decomposed into fixed, combustible gases.

Typical analyses of gases made from the same fuels in the up-draft (U. D.) and down-draft (D. D.) producer, the percentages being by volume, are given in the preceding table.

In the matter of steam raising it is questionable if better results are obtained by using the gas made from the coal than by firing the coal directly under the boilers, especially in the case of good grades of coal from subbituminous to anthracite, but many fuels, notably peat and some of the true lignites, that give indifferent results when fired directly under a steam boiler, give most excellent results when fired as gas. Further, almost any material containing carbon will yield fuel gas in the producer, even bituminous shale, saw-dust, wood pulp, cornstalks, and the like. It is practically impossible to predicate the yield of gas and the quality thereof of a coal from its analysis. Tests in the various types of producers are required for this purpose.

Strictly speaking, the gaseous fuels previously described are all producer gases, except natural gas, coal gas (illuminating gas), and the waste heat gases from beehive coke ovens. These various producer gases are not commonly used for steam raising under boilers, but are a direct source of power in internal combustion engines. It must be noted that as carbon monoxide is one of the most important heat-producing constituents of all these gases, extreme caution must be observed in inhaling them owing to their highly poisonous nature.

## STEAM

### PROPERTIES OF STEAM

**Saturated Steam.**—If water is put in a closed vessel and heat is applied until boiling occurs and steam is given off, the pressure and the temperature of the steam will be the same as those of the water. The steam thus produced is known as *saturated steam;* that is, saturated steam is steam whose temperature is the same as that of boiling water subjected to the same pressure. Its nature is such that any loss of heat will cause some of the steam to condense, provided the pressure is not changed. Saturated steam that carries no water particles with it is called *dry saturated steam;* if it contains moisture it is called *wet steam.* At every different pressure, saturated steam has certain definite values for the temperature, the weight per cubic foot, the heat per pound, and so on. These various values, collected and arranged in order, form the table of the Properties of Saturated Steam, more commonly termed the Steam Table, which is given on the following pages.

The various properties of steam, with their symbols, as given in the Steam Table, are as follows:

The temperature, $t$, of the steam, which is the boiling point of the water from which the steam is formed.

The *heat of the liquid*, $q$, which is the number of British thermal units required to raise the temperature of 1 lb. of water from 32° F. to the boiling point corresponding to the given pressure.

The *latent heat of vaporization*, $r$, often termed the *latent heat*, which is the number of British thermal units required to change 1 lb. of water at the boiling point into steam at the same temperature.

The *total heat of vaporization*, $H$, often termed the *total heat*, which is the number of British thermal units required to raise 1 lb. of water from 32° F. to the boiling point for any given pressure and to change it into steam at that pressure. It is the sum of the heat of the liquid and the latent heat.

The *specific volume*, $V$, which is the volume, in cubic feet, of 1 lb. of steam at the given pressure.

The *density*, $w$, which is the weight, in pounds, of 1 cu. ft. of steam at the given pressure. It is the reciprocal of the specific volume.

## PROPERTIES OF SATURATED STEAM

| $p$ | $t$ | $q$ | $H$ | $r$ | $V$ | $w$ |
|---|---|---|---|---|---|---|
| 1 | 101.99 | 70.0 | 1,113.1 | 1,043.0 | 334.6 | .00299 |

The pressures, $p$, given in the first column are absolute pressures. The pressure registered by the gauge on the boiler is the *gauge pressure*, or the pressure of the steam above that of the atmosphere. The pressure of the atmosphere at sea level, with the barometer at about 30 in., is approximately 14.7 lb. per sq. in. Therefore, the *absolute* pressure at sea level is equal to the gauge pressure plus 14.7. In using the Steam Table, the atmospheric pressure, 14.7 lb. per sq. in., must always be added to the gauge pressure.

**Use of Steam Table.**—For any absolute pressure $p$ given in the first column of the Steam Table, the corresponding temperature $t$, total heat $H$, or other property is found in the same horizontal line, under the proper column heading; but if the pressure lies between two of the values given in the first column, the corresponding temperature, total heat, etc. must be found by interpolation, as illustrated in the following examples:

EXAMPLE 1.—Find the temperature corresponding to a pressure of 147 lb. per sq. in., absolute.

SOLUTION.—Referring to the Steam Table,

$$\begin{array}{ll} \text{for } p = 150 \text{ lb., } t = 358.26° \\ \text{and} \qquad\qquad \text{for } p = 145 \text{ lb., } t = 355.59° \\ \hline \text{Difference, 5 lb.,} \qquad 2.67° \end{array}$$

Difference for 1 lb. difference of pressure is $2.67° \div 5 = .534°$. 147 lb. − 145 lb. = 2 lb., the given difference of pressure; and for this, the difference in temperature is $2 \times .534° = 1.068°$ or $1.07°$, taking two decimal places. Hence, the increase of 2 lb. from 145 lb. to 147 lb. is accompanied by an increase in temperature of $1.07°$. Therefore, adding the increase $1.07°$ to the temperature $355.59°$ corresponding to 145 lb., the temperature for 147 lb. is $355.59° + 1.07° = 356.66°$.

EXAMPLE 2.—The pressure in a steam boiler as shown by the gauge is 87 lb. per sq. in. What is the temperature of the steam?

SOLUTION.—The absolute pressure is $87 + 14.7 = 101.7$ lb. per sq. in. This pressure, in the Steam Table, lies between the values 100 and 105.

$$\begin{array}{ll} \text{for } p = 105 \text{ lb., } t = 331.13° \\ \text{for } p = 100 \text{ lb., } t = 327.58° \\ \hline \text{Difference, 5 lb.,} \qquad 3.55° \end{array}$$

For 1 lb. change of pressure, the difference in temperature is $3.55° \div 5 = .71°$. From 100 lb. to 101.7 lb., the change of pressure is 1.7 lb., and the corresponding change of temperature is $.71° \times 1.7 = 1.207°$, or $1.21°$ as the values in the Steam Table contain but two decimal places. For 101.7 lb., therefore, the temperature is $327.58° + 1.21° = 328.79°$.

EXAMPLE 3.—What is the pressure of steam at a temperature of 285° F.?

SOLUTION.—From the Steam Table,

for $t = 285.72°$, $p = 54$ lb.
for $t = 283.32°$, $p = 52$ lb.

Difference, 2.40°,     2 lb.

From $t = 283.32°$ to $t = 285°$, the increase of temperature is $1.68°$. Now, as an increase of temperature of 2.40° gives an increase of pressure of 2 lb., the increase of 1.68° must give an increase of pressure of

$$\frac{1.68}{2.40} \times 2 \text{ lb.} = 1.4 \text{ lb.}$$

Hence, the required pressure is 52 lb. $+ 1.4$ lb. $= 53.4$ lb.

EXAMPLE 4.—Find, from the Steam Table, the total heat of 1 lb. of saturated steam at a pressure of 63 lb. per sq. in., gauge.

SOLUTION.—The absolute pressure is $63 + 14.7 = 77.7$ lb. per sq. in. From the Steam Table,

for $p = 78$ lb., $H = 1,176.5$ B. T. U.
for $p = 76$ lb., $H = 1,176.0$ B. T. U.

Difference, 2 lb.,     .5 B. T. U.
Difference, 1 lb.,     .25 B. T. U.

The difference between the given pressure and 76 lb. is $77.7 - 76 = 1.7$ lb. For a difference of 1.7 lb., the change of total heat is $1.7 \times .25 = .425$ B. T. U. Hence, for 77.7 lb., $H = 1,176.0 + .425 = 1,176.425$, say 1,176.4 B. T. U.

EXAMPLE 5.—Find the volume occupied by 14 lb. of steam at 30 lb. gauge pressure.

SOLUTION.—Absolute pressure $= 30 + 14.7 = 44.7$ lb. per sq in. From the Steam Table,

for $p = 44$ lb., $V = 9.484$ cu. ft.
for $p = 46$ lb., $V = 9.097$ cu. ft.

Difference, 2 lb.,     .387 cu. ft.

The difference for 1 lb. is $.387 \div 2 = .1935$. $44.7 - 44 = .7$ lb. actual difference in pressure. $.1935 \times .7 = .135$ difference in volume. As the pressure increases, the volume decreases; and to obtain the volume at 44.7 lb., it is necessary to subtract the difference .135 from the volume at 44 lb.; thus, for $p = 44.7$, $V = 9.484 - .135 = 9.349$ cu. ft. The volume of 14 lb. is $14 \times 9.349$ cu. ft. $= 130.89$ cu. ft.

EXAMPLE 6.—Find the weight of 40 cu. ft. of steam at a temperature of 254° F.

SOLUTION.—From the Steam Table, the weight $w$ of 1 cu. ft. of steam at 253.98 is .07820 lb. $254 - 253.98 = .02$. Neglecting the .02°, the weight of 40 cu. ft. is therefore $.07820 \times 40 = 3.128$ lb.

EXAMPLE 7.—How many pounds of steam at 64 lb. pressure, absolute, are required to raise the temperature of 300 lb. of water from 40° to 130° F., the water and steam being mixed together?

SOLUTION.—The number of heat units required to raise 1 lb. from 40° to 130° is $130° - 40° = 90$ B. T. U. Actually, a little more than 90 would be required but the above is near enough for all practical purposes. Then, to raise 300 lb. from 40° to 130° requires $90 \times 300 = 27,000$ B. T. U. This quantity of heat must necessarily come from the steam. Now, 1 lb. of steam at 64 lb. pressure gives up, in condensing, its latent heat of vaporization, or 906.2 B. T. U.; but, in addition to its latent heat, each pound of steam on condensing must give up an additional amount of heat in falling to 130°. As the original temperature of the steam was 296.74° F. (see Steam Table), each pound gives up by its fall of temperature $296.74 - 130 = 166.74$ B. T. U. Consequently, each pound of the steam gives up a total of $906.2 + 166.74 = 1,072.94$ B. T. U., and $27,000 \div 1,072.94 = 25.16$ lb. of steam will therefore be required to accomplish the desired result.

## SUPERHEATED STEAM

If saturated steam in contained in a vessel, out of contact with water, and heat is added to it, its temperature will begin to rise and its weight per cubic

foot will begin to decrease, provided the pressure remains constant. As more heat is added, the temperature rises farther above that of saturated steam at that pressure, and the steam is then called *superheated steam*. Superheated steam cannot exist in contact with water.

The following distinction is usually made between saturated and superheated steam: For a given pressure, saturated steam has one temperature and one weight per cubic foot, neither of which can change so long as the steam remains in immediate contact with water. Superheated steam at the same pressure has a greater temperature and less weight per cubic foot than saturated steam, and both the temperature and weight per cubic foot may vary while the pressure remains constant if the volume increases or decreases accordingly. In other words, both the pressure and the volume of superheated steam must be constant in order to maintain a constant temperature and a constant weight per cubic foot.

## QUALITY OF STEAM

**Moisture in Steam.**—The steam furnished by the average steam boiler is not dry saturated steam, but is usually wet steam. A good boiler should not show more than 2 or 3% of water in the steam. In a quantity of wet steam, or a mixture of steam and water, the percentage of dry steam, expressed as a decimal, is called the *quality of the steam*. For example, suppose that a certain boiler generates wet steam that contains 3%, or .03, of moisture; then the quality of the steam, or the percentage of dry steam, is .97. In other words, the quality of the steam is equal to 1 minus the percentage of moisture, expressed decimally, or
$$Q = 1 - m,$$
in which $Q$ = quality of steam;

$m$ = percentage of moisture, expressed decimally.

**EXAMPLE.**—What is the quality of steam that contains 2.7% of moisture?

**SOLUTION.**—Expressed as a decimal, 2.7% = .027. Then, substituting this value for $m$ in the formula, $Q = 1 - .027 = .973$.

**Heat in Wet Steam.**—The total heat contained in 1 lb. of dry steam is the sum of the heat required to raise 1 lb. of water from 32° F. to the boiling point and the heat required to change the boiling water into steam of the same temperature. That is, in the Steam Table, each value given in the fourth column is the sum of the values given in the third and fifth columns and lying in the same horizontal row. In a mixture of 1 lb. of steam and water at the same temperature there is less heat than in 1 lb. of dry steam at the same temperature; for all the water has not been changed to steam, and consequently the latent heat of 1 lb. of steam has not been utilized. Instead, there is present only that part of the latent heat which is used to evaporate the portion of the mixture that is dry steam, which is represented by the quality of the steam. Thus, using the symbols given in the Steam Table,
$$H = q + r \quad (1)$$
which is the formula for the total heat of 1 lb. of dry steam. But if the steam is wet, and $Q$ represents the quality of the steam, expressed decimally, the total heat of 1 lb., represented by $H_1$, is
$$H_1 = q + Qr \quad (2)$$

**EXAMPLE.**—What is the total heat of 10 lb. of steam at 150 lb. gauge pressure, if the steam contains 5% of moisture?

**SOLUTION.**—From the Steam Table, the heat of the liquid of 1 lb. of dry steam at 150 lb., gauge, or 150 + 14.7 = 164.7 lb., absolute, is $q$ = 337.84 B. T. U., and the latent heat of 1 lb. at the same pressure is $r$ = 855.71 B. T. U. As the moisture is 5%, the quality of the steam is 1.00 − .05 = .95. Then, applying formula 2, $H_1$ = 337.84 + .95 × 855.71 = 1,150.76 B. T. U.

## FLOW OF STEAM

**Weight of Steam Discharged.**—The number of pounds of steam that will flow continuously through a pipe of given diameter in 1 min. at specified pressure may be calculated by the formula
$$W = 87 \sqrt{\frac{w(P_1 - P_2)d^5}{L\left(1 + \dfrac{3.6}{d}\right)}},$$
in which $W$ = weight of steam discharged, in pounds per minute;

$w$ = weight of 1 cu. ft. of steam at pressure $P_1$;

$P_1$ = pressure of steam at entrance to pipe, in pounds per square inch;

$P_2$ = pressure of steam at discharge, in pounds per square inch;

$L$ = length of pipe, in feet;

$d$ = diameter of pipe, in inches.

In applying the preceding formula in determining the diameter of the steam pipe for an engine, it must be remembered that, in steam-engine work, the steam is drawn intermittently from the pipe. Thus, assume that an engine of 100 H. P., consuming 30 lb. of steam per H. P. per hr., cuts off at one-fourth stroke. In that case, the steam consumption per hour would be $100 \times 30 = 3,000$ lb. But as the steam used at each stroke is drawn into the cylinder during only one-fourth of the time required to complete the stroke, the 3,000 lb. of steam flows through the pipe in $\frac{1}{4}$ hr. Then, in order to determine the quantity of steam that would flow continuously at the same velocity at which it flows during admission to the cylinder, the actual steam consumption per hour should be divided by the fraction representing the cut-off and the quotient should be taken as the weight of steam discharged per hour. This value, divided by 60, should be substituted for $w$ in the formula. Thus, in the case mentioned, the amount of steam discharged per hour, flowing continuously at the same velocity as during the admission period, is $3,000 \div \frac{1}{4} = 12,000$, and the value of $W$ to be used in the formula is therefore $12,000 \div 60 = 200$ lb. per min. Knowing the pressures, the length of pipe, and the weight of the entering steam per cubic foot, different values of $d$ may be assumed, until a value is found that will give the necessary discharge $W$. This is the required pipe diameter.

## WEIGHT OF STEAM DELIVERED PER MINUTE THROUGH 100 FT. OF PIPE WITH 1 LB. DROP OF PRESSURE

| Initial Gauge Pressure Pounds per Square Inch | Nominal Diameter of Pipe, in Inches | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | 3 | $3\frac{1}{2}$ | 4 | $4\frac{1}{2}$ | 5 | 6 | 7 | 8 | 9 | 10 |
| | Weight, in Pounds, of Steam Delivered per Minute Through 100 Ft. of Pipe with 1 Lb. Drop of Pressure | | | | | | | | | |
| 70 | 43.2 | 64.5 | 91.7 | 124.3 | 168.7 | 277.2 | 410.5 | 577.2 | 793.3 | 1,051.7 |
| 80 | 45.5 | 68.0 | 96.6 | 130.9 | 177.7 | 292.1 | 432.5 | 608.2 | 835.8 | 1,108.4 |
| 90 | 47.6 | 71.2 | 101.2 | 137.2 | 186.3 | 306.0 | 453.3 | 637.3 | 875.9 | 1,161.3 |
| 100 | 49.7 | 74.3 | 105.7 | 143.2 | 194.4 | 319.8 | 473.0 | 665.1 | 914.1 | 1,211.8 |
| 110 | 51.7 | 77.3 | 109.9 | 148.9 | 202.1 | 332.2 | 491.8 | 691.5 | 950.4 | 1,259.9 |
| 120 | 53.6 | 80.2 | 113.9 | 154.4 | 209.5 | 344.3 | 509.9 | 717.0 | 985.4 | 1,306.3 |
| 130 | 55.4 | 82.9 | 117.8 | 159.7 | 216.7 | 356.1 | 527.4 | 741.6 | 1,019.6 | 1,351.1 |
| 140 | 57.2 | 85.5 | 121.5 | 164.7 | 223.6 | 367.4 | 544.6 | 765.7 | 1,052.9 | 1,393.9 |
| 150 | 58.9 | 88.1 | 125.2 | 169.6 | 230.2 | 378.3 | 560.2 | 787.7 | 1,082.6 | 1,428.1 |

The approximate weights of steam delivered per minute through 100 ft. of pipe of various diameters, with a drop of pressure of 1 lb., are given in the foregoing table. On the whole, these values are slightly higher than those that would be obtained by the foregoing formula for the same conditions. If the drop of pressure is more or less than 1 lb., the value in the table must be multiplied by the square root of the drop, to obtain the discharge. Also, if the length of the pipe is more or less than 100 ft., divide 100 by the length, in feet, and multiply the square root of this quotient by the value given in the table. The following example illustrates this point.

EXAMPLE.—How many pounds of steam will be discharged per minute, with an initial gauge pressure of 120 lb. per sq. in., through a pipe 3 in. in diameter and 400 ft. long, with a drop of pressure of 2 lb.?

SOLUTION.—From the table, the amount discharged through 100 ft. of 3-in. pipe with a drop of 1 lb. and an initial pressure of 120 lb. per sq. in., is 53.6 lb. per min. But as the drop is 2 lb., the table value is multiplied by $\sqrt{2}$ and as the length is 400 ft., it must also be multiplied by $\sqrt{\frac{100}{400}}$. Hence, the discharge for the given conditions will be $53.6 \times \sqrt{2} \times \sqrt{\frac{100}{400}} = 37.9$ lb. per min.

Resistance of Elbows and Valves.—The presence of elbows, bends, and valves in a steam pipe increases the resistance to the flow of steam and thus increases the drop of pressure between the inlet and outlet ends. It has been found that the resistance caused by an elbow or a sharp bend is approximately

the same as the resistance of a length of pipe equal to 60 times the diameter, and that a stop-valve has a resistance equal to that of a length of pipe of 40 diameters. In using the foregoing formula for the weight of steam discharged, therefore, the value of $L$ should be the equivalent length of pipe, taking into account the bends and valves.

EXAMPLE.—What is the equivalent length of 300 ft. of 3-in. pipe containing four elbows and six stop-valves?

SOLUTION.—Each elbow has a resistance the same as that of 60 diameters of pipe, or $60 \times 3 = 180$ in. $= 15$ ft., and four elbows have the resistance of $4 \times 15 = 60$ ft. of pipe. Each stop-valve has a resistance that is equivalent to adding $40 \times 3 = 120$ in. $= 10$ ft. of pipe, and, as there are six valves, their combined resistance is that of $6 \times 10 = 60$ ft. of pipe. The equivalent length of pipe is, therefore, $300 + 60 + 60 = 420$ ft.

**Steam Pipes for Engines.**—In practice, the velocity of flow of steam in the supply pipes of engines and pumps is usually over 6,000 ft. per min., although it is increased to as much as 8,000 ft. per min. in some cases. For exhaust pipes, a common value is 4,000 ft. per min. The assumptions made are that the cylinder is filled with steam at boiler pressure at each stroke and that a volume of steam equal to the volume of the cylinder is released at each stroke, so that the flow is practically continuous. The areas of the steam and exhaust pipes may then be calculated by the formula

$$a = \frac{AS}{s},$$

in which    $a =$ area of steam or exhaust pipe, in square inches;
$A =$ area of cylinder, in square inches;
$S =$ piston speed, in feet per minute;
$s =$ velocity of steam in pipe, in feet per minute.

EXAMPLE.—Find the areas of the steam and exhaust pipes for an engine whose cylinder is 20 in. in diameter and whose piston speed is 450 ft. per min.

SOLUTION.—By the formula, the area of the steam pipe, assuming that $s = 6,000$ ft. per min., is

$$a = \frac{.7854 \times 20^2 \times 450}{6,000} = 23.6 \text{ sq. in}$$

Similarly, for the exhaust pipe, assuming that $s = 4,000$, the area is

$$a = \frac{.7854 \times 20^2 \times 450}{4,000} = 35.3 \text{ sq. in.}$$

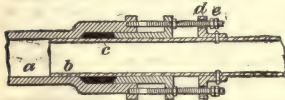
---

# BOILER PIPING

**Principal Considerations.**—The piping of an engine and boiler plant requires that careful attention be paid to all the details as well as to the general design, not only in order to make it suitable for the purpose, but also in order to reduce the likelihood of a breakdown. The main considerations regarding steam piping are the size of the pipes, the arrangement and construction of the piping system, the method of providing for expansion, and proper drainage.

**Materials for Pipes.**—Most of the piping for steam and water is built up of wrought-iron or steel pipe of standard size. The various grades of wrought-iron and steel pipe are known as *standard, extra strong,* and *double extra strong.* Both wrought-iron and steel pipe are used in the piping systems of power plants. Formerly, wrought iron was chiefly used, but of late steel has been employed, especially for the larger sizes of steam pipes. The two kinds are equally reliable when made into expansion bends, copper bends as a general rule being used only for very heavy work.

FIG. 1

**Expansion Joints.**—In installing steam piping, provision must be made for expansion and contraction, which ordinarily amounts to about $1\frac{1}{2}$ in. per 100 ft. of pipe. Generally, this may be provided for in the arrangement of the piping, but for great lengths that are straight, or nearly so, it is necessary to use expansion joints, which may be made in various ways. One form, shown in Fig. 1, is called the *slip joint.* The ends $a$ and $b$ of the sections of pipe come together in a stuffingbox $c$ in order to make a steam-tight joint. The stud bolts are extra long, so as to extend through holes in a flange $d$ riveted to the pipe $b$.


Check-nuts $e$ on the ends of the studs prevent the two ends of the pipe from being forced apart by the steam pressure. The nuts $e$ are not intended ordinarily to be in contact with the flange; their distance from the flange is adjusted so that the proper expansion may occur.

In Fig. 2 is shown a *corrugated expansion joint*, which is sometimes used on large exhaust pipes. It consists of a short section of flanged corrugated pipe, usually copper, which is put in the steam pipe wherever necessary. The elasticity of this section, due to the corrugations, permits expansion and contraction.

FIG. 2

**Expansion Bends.**—The best way of allowing for expansion is by using expansion bends, or bent pipes; but the space they occupy often limits their use. The forms of bends more commonly used are shown in Fig. 3, the trade name being given below each bend. Where a bent pipe is used, the radius $r$ of the bend should not be less than six times the diameter of the pipe, for wrought iron or steel; to secure the proper spring in bends used on long lines of piping, the radius should be greater than this. Bends of copper pipe may be of shorter radius, as copper yields more readily than iron or steel.

Elbow

Return bend

Double bend

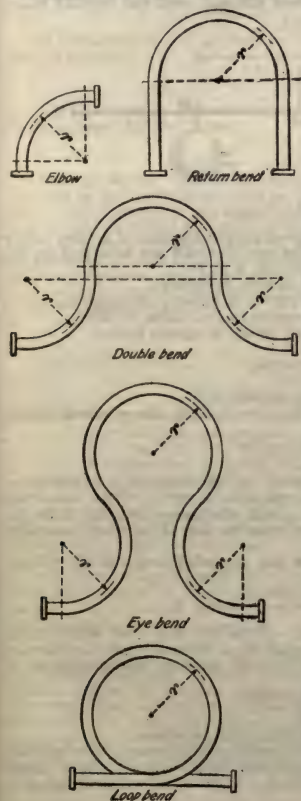
Eye bend

Loop bend

FIG. 3

Bends made from iron or steel pipe must be bent while red hot. Iron and steel pipe bends generally have iron flanges fastened on; copper bends either have composition flanges riveted and brazed on, or have steel flanges, the edges of the pipe being turned over. The piping is usually installed so that it is under a slight tension when cold; when filled with steam, the expansion of the pipes removes the tension, and there is no stress on the pipe except that due to the steam pressure.

**Arrangement of Piping.**—The pipes and fittings must be so proportioned as to permit of free flow of steam or water. Water pockets should be avoided; and where such pockets are unavoidable, they must be drained to free them from water. By-pass pipes should be arranged around feedwater heaters, economizers, pumps, etc. The system must be so designed as to give perfect freedom for expansion and contraction.

Perfect drainage must be provided in order that all water of condensation shall be fully separated from the steam. Reliability is insured by careful design and superior workmanship, combined with the use of high-class materials and fittings and the judicious placing of cut-out and by-pass valves. Drainage is best effected by arranging the piping so that all the water of condensation will flow by gravity toward a point close to the delivery end of the pipe, and then providing a drip pipe at that point. A trap may be placed at the end of the drip pipe for automatic draining.


# BOILER FITTINGS

## SAFETY VALVES

The *safety valve* is a device attached to the boiler to prevent the steam pressure from rising above a certain point. When steam is made more rapidly than it is used, its pressure must necessarily rise; and if no means of escape is provided for it, the result must be an explosion. Briefly described, the safety valve consists of a plate, or disk, fitting over a hole in the boiler shell and held to its place by a dead weight, by a weight on a lever, or by a spring. The weight or the spring is so adjusted that when the steam reaches the desired pressure the disk is raised from its seat, and the surplus steam escapes through the opening in the shell.

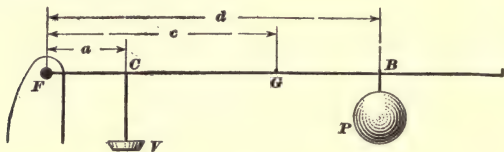


FIG. 1

**Weight of Ball for Lever Safety Valve.**—A simple diagram of a lever safety valve is shown in Fig. 1. The valve stem and the ball are attached to the lever at $C$ and $B$, respectively, and the fulcrum is at $F$.

Let $d = FB =$ distance from fulcrum to weight, in inches;
$c = FG =$ distance from fulcrum to center of gravity of lever, in inches;
$a = FC =$ distance from fulcrum to center line of valve, in inches;
$A =$ area of orifice beneath bottom of valve, in square inches;
$W =$ weight of ball $P$, in pounds;
$W_1 =$ weight of valve and stem, in pounds;
$W_2 =$ weight of lever, in pounds;
$p =$ blow-off pressure, in pounds per square inch.

Then, if the position of the ball $P$ on the lever is fixed, the required weight of the ball may be found by the formula

$$W = \frac{a(pA - W_1) - W_2c}{d}$$

**EXAMPLE.**—The area of the orifice is 10 sq. in., the distance from the valve to the fulcrum is 3 in., and the length of the lever is 32 in. The valve and stem weigh 5 lb., the lever weighs 12 lb., and the gauge pressure is 90 lb. What should be the weight $W$, if placed 2 in. from the end of the lever, assuming the lever to be straight?

**SOLUTION.**—In this case, $c = 32 \div 2 = 16$ in., and $d = 32 - 2 = 30$ in. Then, substituting in the formula,

$$W = \frac{3 \times (90 \times 10 - 5) - 12 \times 16}{30} = 83.1 \text{ lb.}$$

**Position of Ball for Lever Safety Valve.**—If the ball of a lever safety valve has a known weight and it is desired to find at what distance from the fulcrum it must be placed so as to give a required blow-off pressure, the formula to be used is

$$d = \frac{a(pA - W_1) - W_2c}{W}$$

in which the various letters have the same meanings as before.

**EXAMPLE.**—Suppose all the quantities to remain the same as in the solution of the preceding example, except that it is desired that the boiler should blow off at 75 lb. gauge pressure, instead of 90 lb. What will be the distance of the weight from the fulcrum?

**SOLUTION.**—Applying the formula

$$d = \frac{3 \times (75 \times 10 - 5) - 12 \times 16}{83.1} = 24.58 \text{ in.}$$

**Roper's Safety-Valve Rules.**—Some inspectors of the United States Steamboat Inspection Service prefer to have lever safety-valve problems worked

out by the rules that follow, known among American marine engineers as *Roper's rules*.

Let $A$ = area of valve, in square inches;
$D$ = distance from center line of valve to fulcrum, in inches;
$L$ = distance of weight from fulcrum, in inches;
$P$ = steam pressure, in pounds per square inch;
$W$ = weight of load or weight on lever, in pounds;
$V$ = weight of valve and stem, in pounds;
$w$ = weight of lever, in pounds;
$l$ = distance from fulcrum to center of gravity of lever, in inches.

Then, the pressure at which the safety-valve will blow off is found by the formula

$$P = \frac{WL + wl + VD}{AD} \qquad (1)$$

If the distance $L$ is known, the weight $W$ to be hung on the lever is found by the formula

$$W = \frac{APD - (wl + VD)}{L} \qquad (2)$$

The distance $L$ from the fulcrum to the point at which the weight $W$ is hung is found by the formula

$$L = \frac{APD - (wl + VD)}{W} \qquad (3)$$

**Area of Safety Valve.**—By area of safety valve is meant the area of the opening in the valve seat; that is, the area of the surface of the valve in contact with steam when the valve is closed. The size of the valve relative to the size of the boiler and the working pressure is prescribed by law in many localities, and must be made to conform to the law wherever such law is in existence. In localities having no law governing this matter, the size of the safety valve may be calculated by the accompanying formulas, which are based on practice and recommended by leading authorities.

For natural draft,

$$A = \frac{22.5G}{p + 8.62} \qquad (1)$$

For artificial draft,

$$A = \frac{1.406 \, w}{p + 8.62}, \qquad (2)$$

in which $G$ = grate surface, in square feet;
$p$ = steam, gauge pressure, in pounds per square inch;
$w$ = weight of coal burned per hour, in pounds;
$A$ = least area of safety valve, in square inches.

**Location of Safety Valve.**—The safety valve should be placed in direct connection with the boiler, so that there can be no possible chance of cutting off the communication between them. A stop-valve placed between the boiler and the safety valve is a very fruitful cause of boiler explosions. Again, the safety valve must be free to act, and to prevent it from corroding fast to its seat, it should be lifted from the seat occasionally. Care must be taken to prevent persons ignorant of the importance of safety valves from raising the blow-off pressure by adding to the weights or increasing the tension of the spring. To this end, the weights of lever safety valves are often locked in position by the boiler inspector.

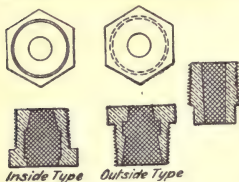
## FUSIBLE PLUGS

*Fusible plugs* are devices placed in the crown sheets of furnaces, or in similar places, to obviate danger from overheating through lack of water. The plug often consists of an alloy of tin, lead, and bismuth, which melts at a comparatively low temperature. In many localities, the law requires that fusible plugs shall be attached to all high-pressure boilers.

The fusible plugs in common use are shown in section, on the next page. They consist of brass or iron shells threaded on the outside with a standard pipe thread. The plugs have some form of conical filling, the larger end of the filling receiving the steam pressure. The conical form of the filling prevents it from being blown out by the pressure of the steam. Fusible plugs applied from the outside differ from those applied from the inside, as shown.

**Location of Fusible Plugs.**—In the absence of local laws, the following rules issued by the Board of Boiler Rules of the State of Massachusetts may be adopted. Fusible plugs must be filled with pure tin, and the least diameter

shall not be less than $\frac{1}{2}$ in., except for working pressures over 175 lb., gauge, or when it is necessary to place a fusible plug in a tube, in which cases the least diameter of fusible metal shall not be less than $\frac{3}{8}$ in. The location of fusible plugs shall be as follows:

*Inside Type    Outside Type*


In horizontal return-tubular boilers, in the back head, not less than 2 in. above the upper row of tubes and projecting through the sheet not less than 1 in.

In horizontal flue boilers, in the back head, on a line with the highest part of the boiler exposed to the products of combustion, and projecting through the sheet not less than 1 in.

In locomotive-type or star water-tube boilers, in the highest part of the crown sheet and projecting through the sheet not less than 1 in.

In vertical fire-tube boilers, in an outside tube, placed not less than one-third the length of the tube above the lower tube-sheet.

In vertical submerged-tube boilers, in the upper tube-sheet.

In water-tube boilers of the Babcock & Wilcox type, in the upper drum, not less than 6 in. above the bottom of the drum and projecting through the sheet not less than 1 in.

In Stirling boilers of standard type, in the front side of the middle drum not less than 6 in. above the bottom of the drum and projecting through the sheet not less than 1 in.

In Stirling boilers of the superheated type, in the front drum, not less than 6 in. above the bottom of the drum, and exposed to the products of combustion, projecting through the sheet not less than 1 in.

In water-tube boilers of the Heine type, in the front course of the drum, not less than 6 in., from the bottom of the drum, and projecting through the sheet not less than 1 in.

In Robb-Mumford boilers of standard type, in the bottom of the steam and water drum, 24 in. from the center of the rear neck, and projecting through the sheet not less than 1 in.

In water-tube boilers of the Almy type, in a tube directly exposed to the products of combustion.

In vertical boilers of the Climax or Hazleton type, in a tube or center drum, not less than one-half the height of the shell, measuring from the lowest circumferential seam.

In Cahall vertical water-tube boilers, in the inner sheet of the top drum, not less than 6 in. above the upper tube sheet.

In Scotch marine-type boilers, in the combustion-chamber top, and projecting through the sheet not less than 1 in.

In dry-back Scotch-type boilers, in the rear head, not less than 2 in. above the top row of tubes, and projecting through the sheet not less than 1 in.

In Economic-type boilers, in the rear head, above the upper row of tubes.

In cast-iron sectional heating boilers, in a section over and in direct contact with the products of combustion in the primary combustion chamber.

In other types and new designs, fusible plugs shall be placed at the lowest permissible water level, in the direct path of the products of combustion, as near the primary combustion chamber as possible.

## CONNECTION OF STEAM GAUGE

A steam gauge should be connected to the boiler in such a manner that it will neither be injured by heat nor indicate incorrectly the pressure to which it is subjected. To prevent injury from heat, a so-called siphon is placed between the gauge and the boiler. This siphon in a short time becomes filled with water of condensation, which protects the spring of the gauge from the injury the hot steam would cause. Care should be taken not to locate the steam-gauge pipe near the main steam outlet of the boiler, as this may cause the gauge to indicate a lower pressure than really exists. In locating the steam gauge, care must also be taken not to run the connecting pipe in such a manner that the accumulation of water in it will cause an extra pressure to be shown.

## BLOW-OFFS

For the double purpose of emptying the boiler when necessary and of discharging the loose mud and sediment that collect from the feedwater, every boiler is provided with a pipe that enters the boiler at its lowest point. This

pipe, which is provided with a valve or a cock, is commonly known as the *bottom blow-off*. The position of the blow-off pipe varies with the design of the boiler; in ordinary return-tubular boilers, it is usually led from the bottom of the rear end of the shell through the rear wall. Where the boiler is fitted with a mud-drum, the blow-off is attached to the drum.

**Blow-Off Cocks and Valves.**—While in many boiler plants globe valves are used on the blow-off pipe, they have the disadvantage that the valve may be kept from closing properly by a chip of incrustation or similar matter getting between the valve and its seat, with the result that water may leak out of the boiler unnoticed. Plug cocks packed with asbestos are widely used, the asbestos packing obviating the objectionable features of the ordinary plug cock. Gate valves are also used to some extent, but have the same disadvantage as globe valves. In the best modern practice, the blow-off pipe is fitted with two shut-off devices. The one shut-off may be an asbestos-packed cock and the other some form of valve, or both may be cocks or valves, the idea underlying this practice being that leakage past the shut-off nearest the boiler will be arrested by the other.

**Protection of Blow-Off Pipe.**—When exposed to the gases of combustion, the bottom blow-off pipe should always be protected by a sleeve made of pipe, by being bricked in, or by a coil of plaited asbestos packing. If this precaution is neglected, the sediment and mud collecting in the pipe, in which there is no circulation, will rapidly become solid. The blow-off pipe should lead to some convenient place entirely removed from the boiler house and at a lower level than the boiler. Sometimes it may be connected to the nearest sewer. In many localities, however, ordinances prohibit this practice; the blow-off is then connected to a cooling tank, whence the water may be discharged into the sewer.

## FURNACE FITTINGS

**Bridge Wall.**—The bridge, also termed the *bridge wall*, is a low wall at the back end of the grate; it forms the rear end of the furnace and causes the flame to come into close contact with the heating surface of the boiler. It is usually built of common brick and faced with firebrick. The passage between the bridge and the boiler shell should not be too small; its area may be approximately one-sixth the area of the grate. The space between the grate and the shell should be ample for complete combustion, and the distance between the grate and the boiler shell may be made about one-half the diameter of the shell.

**Fixed Grates.**—The grate, which is nearly always made of cast iron, furnishes a support for the fuel to be burned and must be provided with spaces for the admission of air. The area of the solid portion of the grate is usually made nearly equal to the combined area of the air spaces.

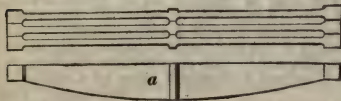


**FIG. 1**

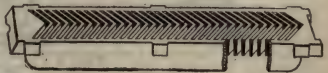
The common type of fixed grate is made of single bars *a*, Fig. 1, placed side by side in the furnace. The thickness of the lugs cast on the sides of the bars determines the width of the open spaces of the grate. It is the general practice to make the thickness across the lugs twice the thickness of the top of the bar. For long furnaces, the bars are generally made in two lengths of about 3 ft. each, with a bearing bar in the middle of the grate. Long grates are generally set with a downward slope toward the bridge wall of about ⅜ in. per ft. of length.

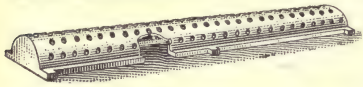
For the larger sizes of anthracite and bituminous coal, the air space may be from ⅜ to ½ in. wide, and the grate bar may have the same width. For pea and nut coal, the air space may be from ⅜ to ¼ in., and for finely divided fuel, like buckwheat, rice, bird's-eye, culm, and slack, air spaces from ³⁄₁₆ to ⅛ in. may be used.

**FIG. 2**

The grate bar shown in Fig. 2, and known as the *herring-bone grate bar*, has in many places superseded the ordinary grate bar, because it will usually far outlast a set of ordinary grate bars. Herring-bone grate bars can be obtained in a great variety of styles and with different widths of air spaces. They are usually supported on cross-bars, and, like many other forms of grate


bars, may be arranged with trunnions, so as to rock the individual bars by means of hand levers.

A form of cast-iron grate bar for the burning of sawdust is shown in Fig. 3. The bar is semicircular in cross-section and is provided with circular openings for the introduction of air. Lugs are cast on each side of the bar to serve as distance pieces in providing air spaces between the bars.

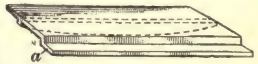
**FIG. 3**


**Dead Plate.**—The front ends of the grate bars are usually supported on the dead plate, which is a flat cast-iron plate placed across the furnace just inside the boiler front and on a level with the bottom of the furnace door. The purpose of the dead plate is twofold: It forms a support for the firebrick lining of the boiler front, and a resting place on which bituminous coal may be coked before it is placed on the fire. To support the grate bars, the inner edge of the dead plate is either beveled or a lip is provided, as at a, Fig. 4.

**Objection to Stationary Grate Bars.**—The greatest objection to stationary grate bars is that with them the furnace door must be kept open for a considerable length of time when the fire is being cleaned. Cleaning fires when the boiler has a stationary grate not only severely taxes the fireman, but the inrush of cold air chills the boiler plates, thus producing stresses that in the course of time will crack them.

**Shaking Grates.**—There are on the market many designs of shaking grates for large steam boilers, differing chiefly in detail and arrangement. Usually the grate bars are hung on trunnions at each end and are connected together with bars to which are attached shaking rods that extend forwards through the furnace front. Levers or handles are attached to the shaking rods, and by working them back and forth the grate bars

**FIG. 4**

receive a rocking motion that breaks up the bed of coal on the grate and serves to shake the ashes through into the ash-pit. The fires may thus be kept clean without the necessity of opening the fire-doors.


**Classes of Mechanical Stokers.**—A mechanical stoker is a power-driven rocking grate arranged so as to give a uniform feed of coal and to rid itself continuously of ashes and clinkers. The principal designs of mechanical stokers and automatic furnaces may be divided into two general classes, *overfeed* and *underfeed*.

**Overfeed Stoker.**—In overfeed stokers the fixed carbon of the coal is burned on inclined grates. The coal is pushed on to these grates, which are given a sufficiently rapid vibratory motion to feed it down at such a rate that practically all the carbon is burned before reaching the lower end, where the ashes and clinkers are discharged. In Fig. 5 is shown a sectional view of a stoker of this class. The coal is fed into the hopper a, from which it is pushed by the pusher plate b on to the dead plate c, where it is heated. From c it passes to the grate d. Each bar is supported at its ends by trunnions and is connected by an arm to a rocker bar i, which is slowly moved to and fro by an eccentric on the shaft s, so as to rock the grates back and forth; the grates thus gradually move the burning fuel downwards. The ashes and clinkers are discharged from the lower grate bar on to the dumping grate e. A guard f may be raised, as shown by the dotted lines, so as to prevent coke or coal from falling from the grate bars into the ash-pit when the dumping grate is lowered.

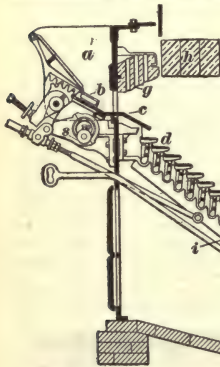


**FIG. 5**

Air for burning the gases is admitted in small jets through holes in the air tile *g*, and the mixture of gas and air is burned in the hot chamber between the firebrick arch *h* and the bed of burning coke below.

**Underfeed Stoker.**—The stoker shown in Fig. 6 illustrates the principle of operation and the construction of the underfeed stoker. Coal is fed into the hopper *a*, from which it is drawn by the spiral conveyer *b* and forced into the magazine *d*. The incoming supply of fresh coal forces the fuel upwards to the surface and over the sides of the magazine on the grates, where it is burned. A blower forces air through a pipe *f* into the chamber *g* surrounding the maga-

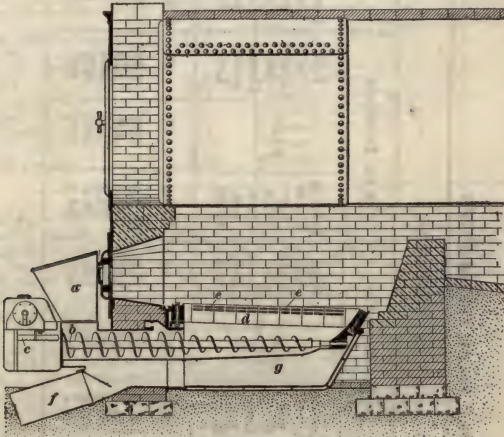

Fig. 6

zine. From *g* the air passes upwards through hollow-cast iron tuyère blocks and out through the openings, or tuyères *e*. The gas formed in the magazine, mixed with the jets of air from the tuyères, rises through the burning fuel above, where it is subjected to a sufficiently high temperature to secure its combustion. Nearly all the air for burning the coal is supplied through the tuyères, only a very small portion of the supply coming through the grate. The ashes and clinkers are gradually forced to the sides of the grate against the side walls of the furnace, from which they are removed from time to time through doors in the furnace front similar to the fire-doors of an ordinary furnace. In other words, owing to the construction of the underfeed stoker, the fire must periodically be cleaned from clinkers and the ashes removed by hand.

# COVERING FOR BOILERS, STEAM PIPES, ETC.

The losses by radiation from uncovered pipes and vessels containing steam are considerable, and in the case of pipes leading to steam engines, are magnified by the action of the condensed water in the cylinder. It therefore is important that such pipes should be well protected. The accompanying table gives the loss of heat from steam pipes naked, and covered with wool or hair felt of different thickness, the steam pressure being assumed at 75 lb., and the exterior air at 60°.

There is a wide difference in the value of different substances for protection from radiation, their values varying nearly in the reverse ratio to their conducting power for heat, up to their ability to transmit as much heat as the surface of the pipe will radiate, after which they become detrimental, rather than useful, as covering. This point is reached nearly at baked clay or brick.

## LOSS OF HEAT FROM STEAM PIPES

Outside Diameter of Pipe, Without Felt

| Thickness of Covering Inches | 2 In. Diameter | | | 4 In. Diameter | | | 6 In. Diameter | | | 8 In. Diameter | | | 12 In. Diameter | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | Loss in Units per Foot Run per Hour | Ratio of Loss | Feet in Length per Horse-power Lost | Loss in Units per Foot Run per Hour | Ratio of Loss | Feet in Length per Horse-power Lost | Loss in Units per Foot Run per Hour | Ratio of Loss | Feet in Length per Horse-power Lost | Loss in Units per Foot Run per Hour | Ratio of Loss | Feet in Length per Horse-power Lost | Loss in Units per Foot Run per Hour | Ratio of Loss | Feet in Length per Horse-power Lost |
| 0 | 219.0 | 1.00 | 132 | 390.8 | 1.00 | 75 | 624.1 | 1.000 | 46 | 729.8 | 1.000 | 40 | 1,077.4 | 1.000 | 26 |
| ¼ | 100.7 | .46 | 288 | 180.9 | .46 | 160 | 187.2 | .300 | 154 | 219.6 | .301 | 132 | 301.7 | .280 | 92 |
| ½ | 65.7 | .30 | 441 | 117.2 | .30 | 247 | 111.0 | .178 | 261 | 128.3 | .176 | 225 | 185.3 | .172 | 157 |
| 1 | 43.8 | .20 | 662 | 73.9 | .18 | 392 | 66.2 | .106 | 438 | 75.2 | .103 | 385 | 98.0 | .091 | 294 |
| 2 | 28.4 | .13 | 1,020 | 44.7 | .11 | 648 | 41.2 | .066 | 703 | 46.0 | .063 | 630 | 60.3 | .056 | 486 |
| 4 | 19.8 | .09 | 1,464 | 28.1 | .07 | 1,031 | 33.7 | .054 | 860 | 34.3 | .047 | 845 | 45.2 | .042 | 642 |
| 6 | | | | 23.4 | .06 | 1,238 | | | | | | | | | |

A smooth or polished surface is of itself a good protection, polished tin or Russia iron having a ratio, for radiation, of 53 to 100 for cast iron. Mere color makes but little difference.

## CONDUCTING POWER OF VARIOUS SUBSTANCES
### (From Péclet)

| Substance | Conducting Power | Substance | Conducting Power |
|---|---|---|---|
| Blotting paper | .274 | Wood, across fiber | .83 |
| Eiderdown | .314 | Cork | 1.15 |
| Cotton or wool, any density | .323 | Coke, pulverized | 1.29 |
|  |  | India rubber | 1.37 |
| Hemp, canvas | .418 | Wood, with fiber | 1.40 |
| Mahogany dust | .523 | Plaster of Paris | 3.86 |
| Wood ashes | .531 | Baked clay | 4.83 |
| Straw | .563 | Glass | 6.60 |
| Charcoal powder | .636 | Stone | 13.68 |

Hair or wool felt has the disadvantage of becoming soon charred from the heat of steam at high pressure, and sometimes of taking fire therefrom. This has led to a variety of cements for covering pipes—composed generally of clay mixed with different substances, as asbestos, paper fiber, charcoal, etc. A series of careful experiments, made at the Massachusetts Institute of Technology showed the condensation of steam in a pipe covered by one of them, as compared with a naked pipe, and one covered with hair felt, was 100 for the naked pipe, 67 for the cement covering, and 37 for the hair felt.

The presence of sulphur in the best coverings and its recognized injurious effects make it imperative that moisture be kept from the coverings, for, if present, it will surely combine with the sulphur, thus making it active. Stated in other words, the pipes and coverings must be kept in good repair. Much of the inefficiency of coverings is due to the lack of attention given them; they are often seen hanging loosely from the pipe that they are supposed to protect.

## RELATIVE VALUE OF NON-CONDUCTORS
### (From Chas. E. Emery, Ph. D.)

| Material | Value | Material | Value |
|---|---|---|---|
| Loose wool | 3.35 | Wood, across the grain | .40 to .55 |
| Loose lampblack | 1.12 | Loam, dry and open | .55 |
| Goose feathers | 1.08 | Chalk, ground | .51 |
| Felt, hair or wool | 1.00 | Coal ashes | .35 to .49 |
| Carded cotton | 1.00 | Gas-house carbon | .47 |
| Charcoal from cork | .87 | Asbestos paper | .47 |
| Mineral wool | .68 to .83 | Paste of fossil meal and asbestos | .47 |
| Fossil meal | .66 to .79 |  |  |
| Straw rope, wound spirally | .77 | Asbestos, fibrous | .36 |
| Rice chaff, loose | .76 | Plaster of Paris, dry | .34 |
| Carbonate of magnesia | .67 to .76 | Clay, with vegetable fiber | .34 |
| Charcoal from wood | .63 to .75 | Anthracite powdered | .29 |
| Paper | .50 to .74 | Coke, in lumps | .27 |
| Cork | .71 | Air space, undivided | .14 to .22 |
| Sawdust | .61 to .68 | Sand | .17 |
| Paste of fossil meal and hair | .63 | Baked clay, brick | .07 |
| Wood ashes | .61 | Glass | .05 |
|  |  | Stone | .02 |

The preceding table is deduced from tests of raw materials contained in commercial pipe coverings and does not indicate the relative values of coverings into whose composition they enter. Mineral wool, a fibrous material made from blast-furnace slag, is a good protection, and is incombustible. Cork chips, cemented together with water glass make one of the best coverings known.

A cheap jacketing for steam pipes, but a very efficient one, may be applied as follows: First, wrap the pipe in asbestos paper, though this may be dispensed with; then lay from 6 to 12 strips of wood lengthwise, according to size of pipe, binding them in position with wire or cord, and around the framework thus constructed wrap roofing paper, fastening it by paste or twine. For flanged pipe, space may be left for access to the bolts, which space should be filled with felt. If exposed to weather, tarred paper should be used or the exterior should be painted. A French plan is to cover the surface with a rough flour paste, mixed with sawdust until it forms a moderately stiff dough. It should be applied with a trowel, in four or five layers each $\frac{1}{4}$ in. thick. If iron surfaces are well cleaned from grease, the adhesion is perfect; for copper, a hot solution of clay in water should be applied. A coating of tar renders the composition impervious to the weather.

---

## BOILER FEEDING AND FEEDWATER

### INJECTORS

**Classification of Injectors.**—Injectors may be divided into two general classes, namely, non-lifting and lifting injectors. *Non-lifting injectors* are intended for use where there is a head of water available. When the water comes to a non-lifting injector under pressure, as from a city main, it can be placed in almost any convenient position close to the boiler. *Lifting injectors* are of two distinct types, called *automatic injectors* and *positive injectors*. As positive injectors generally have two sets of tubes, they are frequently called *double-tube injectors*. Automatic injectors are so called from the fact that they will automatically start again in case the jet of water is broken by jarring or other means. Positive, or double-tube injectors are provided with two sets of tubes, one set of which is used for lifting the water, and the other set for forcing the water thus delivered to it into the boiler. A positive injector has a wider range than an automatic injector and will handle a hotter feed-water supply; it will also lift water to a greater height than the automatic injector.

**Advantages and Disadvantages of Injectors.**—The advantages of the injector as a boiler feeding apparatus are its cheapness, compared with a pump of equal capacity; it occupies but little space; the repair bills are low, owing to the absence of moving parts; no exhaust piping is required, as with a steam pump; it delivers hot water to the boiler.

The disadvantages of the injector are that it will not start with a steam pressure less than that for which it is designed, and that it will stand but little abuse, being poorly adapted for handling water containing grit or other matter liable to cut the nozzles.

**Size of Injector.**—Most engineers prefer to select a size of injector having a capacity per hour about one-half greater than the maximum evaporation per hour in order to have some reserve capacity. The maximum evaporation,

### WATER DELIVERED BY INJECTORS

| Diameter of Throat Decimals of an Inch | Delivery, in Gallons per Hour, with a Pressure per Square Inch of | | | | |
|---|---|---|---|---|---|
| | 30 Lb. | 45 Lb. | 60 Lb. | 75 Lb. | 90 Lb. |
| .10 | 56 | 69 | 80 | 89 | 98 |
| .15 | 127 | 156 | 180 | 201 | 221 |
| .20 | 226 | 278 | 321 | 360 | 393 |
| .25 | 354 | 434 | 502 | 561 | 615 |
| .30 | 505 | 624 | 722 | 807 | 884 |

when not known, may be estimated in United States gallons by one of the following rules, which hold good for ordinary combustion rates under natural draft:

**Rule I.**—*For plain cylindrical boilers, multiply the product of the length and diameter in feet by 1.3.*

**Rule II.**—*For tubular boilers, either horizontal or vertical, multiply the product of the square of the diameter, in feet, and the length, in feet, by 1.9.*

**Rule III.**—*For water-tube boilers, multiply the heating surface, in square feet, by .4.*

**Rule IV.**—*For boilers not covered by the foregoing rules, multiply the grate surface, in square feet, by 12.*

**Rule V.**—*If the coal consumption, in pounds per hour, is known, it may be taken as representing the number of gallons evaporated per hour.*

No standard method of designating the size of an injector is followed by all makers; therefore, such an instrument must be selected from the lists of capacities published by the different makers.

## WATER REQUIRED PER MINUTE TO FEED BOILERS

| Horsepower of Boiler | Feedwater Gallons | Horsepower of Boiler | Feedwater Gallons | Horsepower of Boiler | Feedwater Gallons | Horsepower of Boiler | Feedwater Gallons | Horsepower of Boiler | Feedwater Gallons |
|---|---|---|---|---|---|---|---|---|---|
| 20 | 1.2 | 60 | 3.6 | 110 | 6.6 | 190 | 11.4 | 400 | 24.0 |
| 25 | 1.5 | 65 | 3.9 | 120 | 7.2 | 200 | 12.0 | 450 | 27.0 |
| 30 | 1.8 | 70 | 4.2 | 130 | 7.8 | 225 | 13.5 | 500 | 30.0 |
| 35 | 2.1 | 75 | 4.5 | 140 | 8.4 | 250 | 15.0 | 600 | 36.0 |
| 40 | 2.4 | 80 | 4.8 | 150 | 9.0 | 275 | 16.5 | 700 | 42.0 |
| 45 | 2.7 | 85 | 5.1 | 160 | 9.6 | 300 | 18.0 | 800 | 48.0 |
| 50 | 3.0 | 90 | 5.4 | 170 | 10.2 | 325 | 19.5 | 900 | 54.0 |
| 55 | 3.3 | 100 | 6.0 | 180 | 10.8 | 350 | 21.0 | 1,000 | 60.0 |

NOTE.—A. S. M. E. standard of 30 lb., or 3.6 gal., per H. P. per hr., evaporated from 100° F., to 70 lb. steam pressure per square inch.

**Location of Injector.**—An injector must always be placed in the position recommended by the maker. There must always be a stop-valve in the steam-supply pipe to the injector. While lifting injectors, when working as such, scarcely need a stop-valve in the suction pipe, it is advisable to supply it. When the water flows to the injector under pressure, a stop-valve in the water-supply pipe is a necessity. A stop-valve and a check-valve must be placed in the feed-delivery pipe, with the stop-valve next to the boiler. The check-valve should never be omitted, even if the injector itself is supplied with one. No valve should ever be placed in the overflow pipe, nor should the overflow be connected directly to the overflow pipe, but a funnel should be placed on the latter so that the water can be seen. This direction does not apply to the inspirator or to any other injector that has a hand-operated, separate over-flow valve. In the inspirator, the overflow pipe is connected directly to the overflow, but the end of the pipe must be open to the air. In general, where the injector lifts water it is not advisable to have a foot-valve in the suction pipe, as it is desirable that the injector and pipe may drain themselves when not in use. A strainer should be placed on the end of the suction pipe.

**Steam Supply to Injector.**—The steam for the injector must be taken from the highest part of the boiler, as it must be supplied with dry steam. Under no consideration should the steam be taken from another steam pipe. The suction pipe should be as straight as possible and must be air-tight. When connecting up an injector, the pipes should be cleaned by being blown out with steam before the connection is made, because if a small bit of dirt gets into the injector it will interfere seriously with its operation.

**Injector Troubles.**—In the following discussion of injector troubles, the suction pipe, strainer, feed-delivery pipe, and check-valve are considered as parts of the injector. When searching for the cause of a trouble, therefore,

the suction and delivery pipes should be carefully inspected as well as the injector.

1. *Failure to Raise Water*—The causes that prevent an injector from raising water are:

*Suction pipe stopped up*, due, generally, to a clogged strainer or to the pipe itself being stopped at some point. In case the suction pipe is clogged, steam should be blown back through the pipe to force out the obstruction.

*Leaks in suction pipe*, which prevent the injector forming the vacuum required to raise the water. To test the suction pipe for air leaks, plug up the end and turn the full steam pressure on the pipe; leaks will then be revealed by the steam issuing therefrom. Have the suction pipe full of water before steam is turned on, as the presence of small leaks will be revealed better by water than by steam.

*Water in the suction pipe too hot;* a leaky steam valve or leaky boiler check-valve and leaky injector check-valve may allow hot water or steam to enter the source of supply and heat the water until the injector refuses to handle it.

*Obstruction in the lifting or combining tubes;* or, the spills (or openings) in the tubes through which the steam and water escape to the overflow may be clogged up with dirt or lime.

2. *Injector Primes But Will Not Force*—In some cases an injector will lift water, but will not force it into the boiler; or, it may force part of it into the boiler and the rest out of the overflow. When it fails to force, the trouble may be due to one or the other of the following causes:

*Choked Suction Pipe or Strainer.*—If the suction pipe or strainer is partly choked, the injector will be prevented from lifting sufficient water to condense all the steam issuing from the steam valve. The uncondensed steam, therefore, will gradually decrease the vacuum in the combining tube until it is reduced so much that the injector will not work. The remedy, when the supply valve is partly closed, is to open it; when the suction pipe is choked, blow out the obstruction.

*Suction Pipe Leaking.*—The leak may not be sufficient to prevent the injector from lifting water, but the quantity lifted may be insufficient to condense all the steam, which, therefore, destroys the vacuum in the combining tube. A slight leak will simply cut down the capacity of the injector. In such a case an automatic injector will work noisily, on account of the overflow valve seating and unseating itself as the pressure in the combining tube varies, due to the leak.

*Boiler Check-Valve Stuck Shut.*—If the boiler check-valve is completely closed, the injector may or may not continue to raise water and force it out of the overflow; this depends on the design of the injector. If the boiler check is partly open, the injector will force some of the water into the boiler and the remainder out of the overflow. In case the check-valve cannot be opened wide, water may be saved by throttling both steam and water until the overflow diminishes, or, if possible, ceases. The steam should be throttled at the valve in the boiler steam connection. If a check-valve sticks, it can sometimes be made to work again by tapping lightly on the cap or on the bottom of the valve body.

*Obstruction in Delivery Tube.*—Any obstruction in the delivery tube will cause a heavy waste of water from the overflow. To remedy this, the tube will have to be removed and cleaned.

*Leaky Overflow Valve.*—A leaky overflow valve is indicated by the boiler check chattering on its seat. To remedy this defect, grind the valve on its seat until it forms a tight joint.

*Injector Choked With Lime.*—It is essential to the proper working of an injector that the interior of the tubes be perfectly smooth and of the proper bore. As in course of time the tubes become clogged with lime, the capacity of the injector decreases until, finally, it refuses to work at all. If the water used is very bad, it is frequently necessary to cleanse the tubes of the accumulated lime. This may be done by putting the parts in a bath consisting of 1 part of muriatic acid to 10 parts of water. The tubes should be removed from it as soon as the gas bubbles cease to be given off.

## INCRUSTATION AND CORROSION

**Incrustation.**—Broadly speaking, any deposit that is formed on the plates and tubes of a boiler is termed *scale*, or *incrustation;* it is caused by impurities that enter with the water and are left behind in the boiler when the water is evaporated. In passing through the soil, water dissolves certain mineral substances, the most important of which are carbonate of lime and sulphate of lime. Other substances frequently present in small quantities are chloride

of sodium, or common salt, and chloride of magnesium. The water also often contains other troublesome substances.

**Impurities in Feedwater.**—Some of the more common impurities found in feedwater, together with their properties, are as follows:

*Carbonate of lime* will not dissolve in pure water, but will dissolve in water that contains carbonic-acid gas. It becomes insoluble and is precipitated in the solid form when the water is heated to about 212° F.; the carbonic-acid gas is driven off by the heat.

*Sulphate of lime* dissolves readily in cold water, but not in hot water. It precipitates in the solid form when the water is heated to about 290° F., corresponding to a gauge pressure of 45 lb.

*Chloride of sodium* will not be precipitated by the action of heat unless the water has become saturated with it. As it generally is present in but very small quantities in fresh water, it will take a very long time for the water in a boiler to become troublesome, and with the ordinary blowing down of a boiler once a week or every 2 wk., there is little danger of the water becoming saturated with it. Consequently, it is one of the least troublesome scale-forming substances contained in fresh water.

*Chloride of magnesium* is one of the worst impurities in water intended for boilers, for while not dangerous as long as the water is cold, it makes the water very corrosive when heated, and when present in large quantities, it attacks the metal and rapidly destroys it.

*Organic matter* by itself may or may not cause the water to become corrosive, but will often cause foaming; when it is present in small quantities in water containing carbonate or sulphate of lime, or both, it usually serves to keep the deposits from becoming hard.

*Earthy matter*, like organic matter, is not dissolved in the water, but is in mechanical suspension. It is very objectionable, especially when it is clay, and when other scale-forming substances are present is liable to form a hard scale resembling Portland cement.

*Acids*, such as sulphuric acid, nitric acid, tannic acid, and acetic acid, are often present in the feedwater. The sulphuric acid is the most dangerous one of these acids, attacking the metal of which the boiler is composed and corroding it very rapidly. The other acids, while not so violent in their action as the sulphuric acid, are also dangerous, and water containing any one should be neutralized when it must be used.

**Formation of Scale.**—The small solid particles due to precipitation of substances in solution or matter in mechanical suspension, remain for a time suspended in the water, especially the carbonate of lime which will float on the surface of the water. These particles will gradually settle on the plates, tubes, and other internal surfaces. A large part of the impurities will be carried by the circulation of the water to the most quiet part of the boiler and there settle and form a scale. In a few weeks, if no means of prevention are used, the inner parts of the boiler may be covered with a crust from $\frac{1}{16}$ to $\frac{1}{2}$ in. in thickness.

**Danger of Scale.**—A scale $\frac{1}{32}$ in. or less in thickness is thought by many to be an advantage, as it protects the plates from the corrosive action of acids in the water. When, however, the scale becomes $\frac{1}{4}$ in. thick or more, heat is transmitted through the plates and tubes with difficulty, more fuel is required, and there is danger of overheating the plates. The chief danger from a heavy incrustation is the liability of overheating the plates and tubes. Scale also prevents a proper examination of the inside of the boiler, as it may hide a dangerously corroded piece of plate or a defective rivet head.

**Scale Containing Lime.**—The carbonate of lime forms a soft, muddy scale, which when dry, becomes fluffy and flourlike. This scale may be easily swept or washed out of the boiler by a hose, provided it is not baked hard and fast. A carbonate scale is much harder to deal with when grease is allowed to enter the boiler. The grease settles and mixes with the floury mass, making a spongy crust that remains in contact with the plates, being too heavy to be carried off by the natural circulation of the water. The sulphate of lime forms a scale that soon bakes to the plates.

**Kerosene as Scale Remover.**—Some substances seem to soften and aid in detaching scale. Of these, kerosene oil has met with much favor. Its action appears to be mechanical rather than chemical, the oil penetrating or soaking through the scale and softening and loosening it. It is somewhat useful, too, in preventing the formation of scale, enveloping the fine particles of the scale-forming substances that, after precipitation, float on the surface of the water for a little while. It seems that this prevents the particles from adhering firmly to one another and to the metal when they finally settle.

**Removal of Scale by Chipping.**—A hard scale, when once formed, is generally removed by chipping it off with scaling hammers and scaling bars; soft scale can be largely removed during running by a periodic use of the bottom and surface blow-offs, and the remainder can usually be washed out and raked out when the boiler is blown down and opened. In order to prevent the scale-forming substances deposited on the metal from baking hard, it is advisable to let the boiler cool down slowly until entirely cold preparatory to blowing off, whenever circumstances permit this to be done. This cooling process will generally take from 24 to 36 hr.

**Removal of Mud.**—Mud and earthy matter by itself will not form any hard scale, but will often do so when carbonate of lime and sulphate of lime are present. An accumulation of such matter can be prevented, and most of it can be removed, by a periodic use of the bottom blow-off, removing any remainder when the boiler is opened.

**Internal Corrosion.**—Corrosion of boiler plates may be defined as the eating away or wasting of the plates due to the chemical action of water. Corrosion may be internal and external. Internal corrosion may present itself as uniform corrosion, pitting or honeycombing, and grooving. In cases of uniform corrosion large areas of plate are attacked and eaten away. There is no sharp line of division between the corroded part and the sound plate. Corrosion often violently attacks the staybolts and rivet heads.

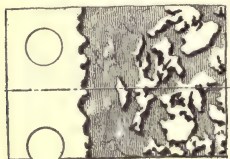

FIG. 1

**Pitting or Honeycombing.**—Pitting or honeycombing of the boiler plates is readily perceived. The plates are indented in spots with holes and cavities from $\frac{1}{32}$ to $\frac{1}{4}$ in. deep. The appearance of a pitted plate is shown in Fig. 1. On the first appearance of pitting, the surface so affected should be thoroughly cleaned and a good coating of thick paint made of red lead and boiled linseed oil should be applied. This treatment should be given from time to time to insure protection to the metal.

**Grooving.**—Grooving, which means the formation of a distinct groove, is generally caused by the buckling action of the plates when under pressure. Thus, the ordinary longitudinal lap joint of a boiler slightly distorts the shell from a truly cylindrical form, and the steam pressure tends to bend the plates at the joint. This bending action is liable to start a small crack along the lap, which, being acted on by corrosive agents in the water, soon deepens into a groove, as shown in Fig. 2.

**External Corrosion.**—External corrosion frequently attacks stationary boilers, particularly those set in brickwork. The causes of external corrosion are dampness, exposure to weather, leakage from joints, moisture arising from the waste pipes or blow-off, etc. External corrosion should be prevented by keeping the boiler shell free from moisture, and the stoppage of all leaks as soon as they appear.

Leakage at rivets and the calking edges of seams may be caused by the delivery of the cold feedwater on to the hot plates; another cause is the practice of emptying the boiler when hot and then filling it with cold water. The leakage in both cases is due to the sudden contraction of the plates.

In horizontal water-tube boilers of the inclined-tube type, external corrosion principally attacks the ends of the tubes, especially the back ends, close up to the headers into which they are expanded. In the course of time this will cause the tubes to leak around the expanded portion in the headers.

FIG. 2

If leaks are attended to as soon as they occur, no corrosion will take place, as the gases of combustion are harmless unless acting in conjunction with water or dampness, or unless the coal is rich in sulphur. Should, however, the ends of several tubes be found badly corroded but not yet leaking from that cause, the tubes should by all means be removed and replaced.

**Lamination.**—Sometimes what is called *lamination*, or the splitting of a plate into thin layers, is revealed by the action of the fire in causing a bag or blister to appear. Laminations due to slag and other impurities in the metal which become flattened out when the plates are rolled, are shown at *a*, Fig. 3.

Under the action of the heat the part exposed to the fire will form a blister which may finally open at the point *b* or *c*. If the laminated portion of the plate is small, it may be cut out and a patch put in its place. If there are a number of laminations in the same plate, it is advisable to put in a new plate.

FIG. 3

**Overheating.**—The heating of a plate beyond its normal temperature is called *overheating*, and may be caused by low water or by incrustation. When the plate is covered by a heavy scale, the plate becomes overheated, so that it yields to the steam pressure, forming a pocket, as shown in Fig. 4, which represents the shell sheet, or the sheet of a horizontal return-tubular boiler directly over the fire. If the pocket is not discovered in time for the repairs to be repaired, it stretches until finally the material becomes too thin to withstand the steam pressure; the pocket then bursts with more or less liability of an explosion. The vegetable or animal oils carried into the boiler from a surface condenser are particularly liable to cause the formation of pockets.

**Prevention of Incrustation and Corrosion.**—Incrustation can best be prevented by purifying the feedwater prior to its entering the boiler, but can be

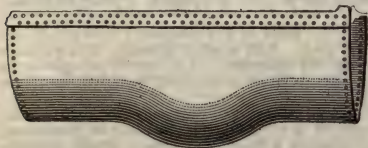

FIG. 4

fairly satisfactorily prevented by a chemical treatment of the water in the boiler. When the water contains large quantities of substances that float on the surface, mechanical means may be resorted to, using the surface blow-off at frequent intervals or some equivalent skimming device. Corrosion is prevented by neutralizing the acids in the water by an alkali. Corrosion due to a perfectly fresh water can be prevented by giving a protective coating to the metal, which may be a thick red-lead paint made up with boiled linseed oil. Sometimes organic substances containing tannic acid, such as oak bark, hemlock, or sumac, are used to loosen or prevent scale. They should not be used, as they are liable to injure the plates by corrosion. The accompanying table gives a list of scale-forming substances and the means of preventing or neutralizing them.

### SCALE-FORMING SUBSTANCES AND THEIR REMEDIES

| Troublesome Substance | Trouble | Remedy or Palliation |
|---|---|---|
| Sediment, mud, clay, etc. | Incrustation | Filtration<br>Blowing off |
| Readily soluble salts | Incrustation | Blowing off<br>Heating feed |
| Bicarbonates of lime, magnesia, iron | Incrustation | Addition of caustic soda, lime, or magnesia |
| Sulphate of lime | Incrustation | Addition of carbonate of soda or barium chloride |
| Chloride and sulphate of magnesium | Corrosion | Addition of carbonate of soda, etc. |
| Carbonate of soda in large amounts | Priming | Addition of barium chloride |
| Acid (in mine water) | Corrosion | Alkali<br>Heating feed |
| Dissolved carbonic acid and oxygen | Corrosion | Addition of caustic soda, slaked lime, etc. |
| Grease (from condensed water) | Corrosion | Slaked lime and filtering<br>Carbonate of soda<br>Substitute mineral oil |
| Organic matter (sewage) | Priming | Precipitate with alum or chloride of iron and filter |
| Organic matter | Corrosion | Same as last |

**Use of Zinc in Boilers.**—Zinc is much used in marine boilers for the prevention of both incrustation and corrosion. The zinc is distributed through the boiler in the form of slabs. About 1 sq. in. of zinc surface should be supplied for every 50 lb. of water in the boiler.

## TESTING OF FEEDWATER

**Testing for Corrosiveness.**—It is a good plan to occasionally test the feedwater and also the water in the boiler for corrosiveness. This may be done by placing a small quantity in a glass and adding a few drops of methyl orange. If the sample of water is acid, and hence corrosive, it will turn pink. If it is alkaline, and hence harmless, it will remain yellow. The acidity may also be tested by dipping a strip of blue litmus paper in the water. If it turns red, the water is acid. This method is not so sensitive as the previous one, which should be used in preference. If litmus paper is kept in stock, it should be kept in a bottle with a glass stopper, as exposure to the atmosphere will cause the paper to deteriorate. If the water in the boilers has become corrosive and corrosion has set in, the water in the gauge glass will show red or even black. As soon as the color is beyond a dirty gray or straw color, it is advisable to introduce lime or soda to neutralize the acid.

**Testing for Carbonate of Lime.**—Pour some of the water to be tested into an ordinary tumbler. Add a little ammonia and ammonium oxalate, and then heat to the boiling point. If carbonate of lime is present, a precipitate will be formed.

**Testing for Sulphate of Lime.**—Pour some of the feedwater into a tumbler and add a few drops of hydrochloric acid. Add a small quantity of a solution of barium chloride and slowly heat the mixture. If a white precipitate is formed, which will not redissolve when a little nitric acid is added, sulphate of lime is present.

**Testing for Organic Matter.**—Add a few drops of pure sulphuric acid to the sample of water. Then add enough of a pink-colored solution of potassium permanganate to make the whole mixture a faint rose color. If the solution retains its color after standing a few hours, no organic substances are present.

**Testing for Matter in Mechanical Suspension.**—Keep a tumblerful of the feedwater in a quiet place. If no sediment is formed in the bottom of the tumbler after standing for a day, there is no mechanically suspended matter in the water.

## PURIFICATION OF FEEDWATER

**Means of Purification.**—Water intended for boilers may be purified by settlement, by filtration, by chemical means, and by heat. Filtration will remove impurities in mechanical suspension, such as oil and grease, and earthy matter, but will not remove substances dissolved in the water. Chemical treatment of the water will render the scale-forming substances and corrosive acids harmless, and may be applied either before or after the water enters the boilers, but preferably the former. Purification by heat is based on the fact that most of the scale-forming substances become insoluble and are precipitated when the water containing them is heated to a high temperature.

**Purification by Settlement.**—For feedwater containing much matter in mechanical suspension, one of the simplest methods of purifying it is to provide a relatively large reservoir, or a large tank for small steam plants, where the impurities can settle to the bottom. While this method is fairly satisfactory in removing earthy matter, it will not clear the water of finely divided organic matter, which is usually lighter than the water and often so finely divided as to be almost dissolved in it.

**Purification by Filtration.**—Organic and earthy matter in mechanical suspension is most satisfactorily removed by a filter, passing the water through layers of sand, gravel, hay, or equivalent substances, or through layers of cloth. Hay and cloth are of service, especially where the feedwater contains oil or grease, as is the case where a surface condenser is used and the condensed steam is used over again.

**Purification by Chemicals.**—Chemical purification may take place before or after the water enters the boiler, the former method being somewhat more expensive. However, the purification is better carried out before the water enters the boiler, as the amount of impurities entering the boiler will be greatly reduced. The process adopted depends on the impurities.

**Use of Quicklime.**—When the water contains only carbonate of lime, it may be treated with slaked quicklime, using 28 gr. of lime for every 50 gr. of lime present in the water, the quicklime precipitating the carbonate of lime and being transformed into carbonate of lime itself during the process.

**Use of Caustic Soda.**—Water containing carbonate of lime may be treated with caustic soda, which precipitates the former and leaves carbonate of soda, which is harmless. For every 100 gr. of carbonate of lime 80 gr. of caustic soda should be added.

**Use of Sal Ammoniac.**—Sal ammoniac is sometimes added to water containing carbonate of lime and will cause the latter to precipitate. Its use is not advisable, however, because if used in excess there is danger of forming hydrochloric acid, which will attack the boiler.

**Treatment for Sulphate of Lime.**—While slaked lime will precipitate carbonate of lime, it will have no effect on sulphate of lime, and water containing the latter, either alone or in conjunction with carbonate of lime, must be treated with other chemicals. The most available chemicals for water containing both are carbonate of soda and caustic soda. These are often fed into the boiler and will precipitate the carbonate and sulphate of lime, requiring the sediment to be blown out or otherwise removed periodically.

**Quantity of Chemicals to Use.**—When treating water containing carbonate and sulphate of lime, caustic soda may be used either by itself or in combination with carbonate of soda, depending on the relative proportions of the lime compounds present in the water. The amount of caustic soda or carbonate of soda to be used per gallon of feedwater can be found as follows:

**Rule I.**—*Multiply the number of grains of carbonate of lime per gallon by 1.36. If this product is greater than the number of grains of sulphate of lime per gallon, only caustic soda is to be used. To find the quantity of caustic soda required per gallon, multiply the number of grains of carbonate of lime in 1 gal. by .8.*

**Rule II.**—*Multiply the number of grains of carbonate of lime per gallon by 1.36. If this product is less than the number of grains of sulphate of lime per gallon, multiply the difference by .78 to obtain the number of grains of carbonate of soda required per gallon. To find the amount of caustic soda required per gallon, multiply the number of grains of carbonate of lime in 1 gal. by .8.*

Example.—A quantitative analysis of a certain feedwater shows it to contain 23 gr. of sulphate of lime and 14 gr. of carbonate of lime per gallon. How much caustic soda and carbonate of soda should be used per gallon to precipitate the scale-forming substances?

Solution.—By rule I, $14 \times 1.36 = 19$ gr. As this product is less than the number of grains of sulphate of lime per gallon, rule II is to be used. Applying rule II, $(23 - 19) \times .78 = 3.12$ gr. of carbonate of soda, and $14 \times .8 = 11.2$ gr. of caustic soda.

**Use of Carbonate of Soda.**—Water containing sulphate of lime, but no carbonate of lime, may be treated with carbonate of soda. The amount of the latter that is required per gallon to precipitate the sulphate of lime is found by multiplying the number of grains per gallon by .78. When using soda, it is well to keep in mind that it will not remove deposited lime from the inside of a boiler. All that the soda can do is to facilitate the separating of the lime, that is, cause it to deposit in a soft state. This sediment must be removed periodically.

**Use of Trisodium Phosphate.**—For decomposing sulphate of lime, tribasic sodium phosphate, more commonly known as trisodium phosphate, is often used. This is claimed to act on the sulphate of lime, forming sulphate of sodium and phosphate of lime, the former of which remains soluble and is harmless, and the latter of which is a loose, easily removed deposit. Trisodium phosphate also acts on carbonate of lime and carbonate of magnesia, forming phosphate of lime and phosphate of magnesia, at the same time neutralizing the carbonic acid released from the carbonate of lime and magnesia, and the sulphuric acid released from the sulphates.

**Neutralization of Acids.**—Acid water can be neutralized by means of an alkali, soda probably being the best one. The amount of soda to be used can best be found by trial, adding soda until the water will turn red litmus paper blue.

**Purification by Heat.**—Carbonate of lime and sulphate of lime become insoluble if the water is heated, the former precipitating at about 212° F. and the latter at about 290° F. This fact is taken advantage of in devices that may be called combined feedwater heaters and purifiers; as they generally use live steam, they are also called *live-steam feedwater heaters.* As no feedwater heater can effect a direct saving of fuel except when the heat is taken from a source of waste, a live-steam feedwater heater can affect the fuel consumption but indirectly. This it does by largely preventing the accumulation of scale in the boiler and the attendant loss in economy due to the lowering of the rate of heat transmission through a plate heavily covered with incrustation.

### FEEDWATER HEATING

The feedwater furnished to steam boilers must be raised from its normal temperature to that of steam before evaporation can commence, and if not otherwise accomplished, it will be done at the expense of fuel that should be utilized in making steam. At 75 lb. gauge pressure, the temperature of boiling water is about 320° F., and if 60° is taken as the average temperature of feedwater, 320 − 60 = 260 B. T. U. is required to raise 1 lb. of water from 60° to 320°. It requires 1,151.5 B. T. U. to convert 1 lb. of water at 60° into steam at 75 lb. gauge pressure, so that the 260 B. T. U. required for heating the water represents 260 ÷ 1,151.5 = 22.6% of the total. All heat taken from a source of waste, therefore, that can be imparted to the feedwater before it enters the boilers is just so much saved, not only in cost of fuel but in boiler capacity.

**Types of Exhaust-Steam Feedwater Heaters.**—The impurities contained in the water will largely determine the type of exhaust-steam heater to be used in any given plant. These heaters are divided into two general classes, namely, open heaters and closed heaters.

An *open heater* is one in which the water space is open to the atmosphere. In a direct-contact open heater, the exhaust steam comes in contact with the water, which, by means of some one of a number of suitable devices, is broken into spray or thin sheets so that it will readily absorb the heat of the steam. In a coil heater, the exhaust steam passes through coils of pipe submerged in a vessel containing the water to be heated, and open at the top.

A *closed heater* is a heater in which the feedwater is not exposed to the atmosphere, but is subjected to the full boiler pressure. The steam does not come in contact with the water; the latter is heated through contact with metallic surfaces, generally those of tubes, that are heated by the exhaust steam.

**Selection of Heater.**—When the boiler feedwater is free from acids, salts, sulphates, and carbonates, so that no scale is formed at a high temperature the closed feedwater heater will be found satisfactory. Heaters of the coil type may be used with pure water, but should not be used with water that will precipitate sediment or scale-forming matter of any kind. The coil heater is very efficient as a heater, as the water circulating through the coils is a long time in contact with the surface surrounded and heated by the exhaust steam. Heaters of the closed type with straight tubes and a sediment chamber can be cleaned more readily than those having curved tubes, but the curved tubes allow more freedom for expansion and contraction. Heaters of the tubular type should have ample sediment chambers and may be used with water that contains organic or earthy matter, but not with water containing scale-forming ingredients. Carbonate of lime is likely to combine with earthy matter and form an exceedingly hard scale.

Heaters of the open exhaust-steam type have the advantage of bringing the exhaust steam in direct contact with the feedwater; some of the exhaust steam is condensed, thus effecting a saving in feedwater, and sediment and scale-forming ingredients, except sulphates of lime and magnesia, are precipitated or will settle to the bottom of the heater. The oil in the exhaust steam must be intercepted by special oil extractors, filters, or skimmers, generally combined with the heater and, by automatic regulation, sufficient fresh feedwater must be added to make up the total quantity required. When the system is properly arranged, all live-steam drips and discharges from traps are led to the heater.

# BOILER TRIALS

**Purposes of Boiler Trials.**—A boiler trial, or boiler test, as it is often called, may be made for one or more of several purposes, the method of conducting the trial depending largely on its purpose. The boiler trial may vary from the simplest one, in which the only observations are the fuel burned and the water fed to the boiler in a stated period of time, to the elaborate standard boiler trial, in which special apparatus and several skilled observers are essential. The object of a boiler trial may be to determine the efficiency of the boiler under given conditions; the comparative value of different boilers working under the same conditions; the comparative value of fuel; or the evaporative power, or horsepower, of the boiler.

**Observations During Trial.**—The essential operations of a boiler trial are the weighing of the feedwater and fuel, and the observation of the steam pressure, temperature of feedwater, and various other less important pressures

and temperatures. These observations should be made simultaneously at intervals of about 15 min.

**Weighing the Coal.**—The coal supplied to the furnace is weighed out in lots of 500 or 600 lb. It is a convenient plan to have a box with one side open placed on a platform scale. A weight is then placed on the scale beam sufficient to balance the box. The scale may then be set at 500 or 600 lb., the coal shoveled in until the beam rises, and then fed directly from the box to the furnace. After the test, the ashes and clinkers must be raked from the ash-pit and grate and weighed. This weight subtracted from the weight of the coal used gives the amount of combustible.

**Measurement of Feedwater.**—The amount of water evaporated in a test for comparative fuel values may be taken as equal to the amount of feedwater supplied without introducing any serious error. The most reliable method of measuring the feedwater delivered to the boilers is to weigh it.

**Standard of Boiler Horsepower.**—When making a horsepower or an efficiency test, a more elaborate method of procedure is required than for a comparative fuel-value test. The reason for this is that different boilers generate steam at different pressures, different feedwater temperatures, and different degrees of dryness; hence, to compare the performances of boilers so as to determine their comparative efficiencies, it is necessary to reduce the actual evaporation to an *equivalent evaporation* from and at 212° F. per lb. of combustible.

A committee of the American Society of Mechanical Engineers has recommended as a commercial horsepower *an evaporation of 30 lb. of water per hr. from a feedwater temperature of 100° F. into steam at 70 lb. gauge pressure*, which is equivalent to $34\frac{1}{2}$ units of evaporation; that is, to $34\frac{1}{2}$ lb. of water evaporated from a feedwater temperature of 212° F. into steam at the same temperature.

As 965.8 B. T. U. is required to evaporate 1 lb. of water from and at 212°, a boiler horsepower is equal to $965.8 \times 34\frac{1}{2} = 33,320$ B. T. U. per hr.

**Equivalent Evaporation.**—The equivalent evaporation is readily determined by means of the formula

$$W_1 = \frac{W(H - t + 32)}{965.8},$$

in which   $W$ = actual evaporation, in pounds of water per hour;
   $H$ = total heat of steam above 32° F. at observed pressure of evaporation;
   $t$ = observed feedwater temperature;
   $W_1$ = equivalent evaporation, in pounds of water per hour, from and at 212° F.

**EXAMPLE.**—A boiler generates 2,200 lb. of dry steam per hr. at a pressure of 120 lb. gauge; the temperature of the feedwater being 70° F.: (*a*) What is the equivalent evaporation? (*b*) What is the horsepower of the boiler?

**SOLUTION.**—(*a*) According to the Steam Table, the total heat $H$ corresponding to a gauge pressure of 120 lb. is 1,188.6 B. T. U. Applying the formula,

$$W_1 = \frac{2,200 \times (1,188.6 - 70 + 32)}{965.8} = 2,621 \text{ lb.}$$

(*b*) The horsepower is obtained by dividing the total equivalent evaporation by 34.5, the equivalent of 1 H. P., and is

$$2,621 \div 34.5 = 76 \text{ H. P., nearly}$$

**Factor of Evaporation.**—The quantity $\dfrac{H - t + 32}{965.8}$ that changes the actual evaporation of 1 lb. of water to the equivalent evaporation from and at 212° F. is called the *factor of evaporation.* To facilitate the calculating of equivalent evaporation, the accompanying table of factors of evaporation is inserted. The equivalent evaporation is found by multiplying the actual evaporation by the factor of evaporation taken from the table.

**EXAMPLE 1.**—A boiler is required to furnish 1,800 lb. of steam per hr. at a gauge pressure of 80 lb.; if the temperature of the feedwater is 48° F., what will be the rated horsepower of the boiler?

**SOLUTION.**—From the table, the factor of evaporation for 80-lb. pressure and a feedwater temperature of 40° is 1.214, and for the same pressure and a feedwater temperature of 50° it is 1.203; the difference is $1.214 - 1.203 = .011$. The difference of temperature is $50° - 40° = 10°$, and the difference between the lower temperature and the required temperature is $48° - 40° = 8°$. Then, $10° : 8° = .011 : x$, or $x = .009$; $1.214 - .009 = 1.205$. $1,800 \times 1.205 = 2,169$ lb., and $2,169 \div 34.5 = 63$ H. P., nearly.

# FACTORS OF EVAPORATION

## Gauge Pressures

Factors of Evaporation

| Temperature of Feedwater Degrees F. | 30 | 40 | 50 | 60 | 70 | 80 | 90 | 100 | 120 | 140 | 160 | 180 | 200 |

| 150 | 1.084 | 1.089 | 1.092 | 1.095 | 1.097 | 1.100 | 1.102 | 1.105 | 1.109 | 1.112 | 1.115 | 1.117 | 1.119 |
| 160 | 1.073 | 1.078 | 1.081 | 1.084 | 1.086 | 1.089 | 1.091 | 1.094 | 1.098 | 1.101 | 1.104 | 1.106 | 1.108 |
| 170 | 1.063 | 1.068 | 1.071 | 1.074 | 1.076 | 1.079 | 1.081 | 1.084 | 1.088 | 1.091 | 1.094 | 1.096 | 1.098 |
| 180 | 1.052 | 1.057 | 1.060 | 1.063 | 1.065 | 1.068 | 1.070 | 1.073 | 1.077 | 1.080 | 1.083 | 1.085 | 1.087 |
| 190 | 1.042 | 1.047 | 1.050 | 1.053 | 1.055 | 1.058 | 1.060 | 1.063 | 1.067 | 1.070 | 1.073 | 1.075 | 1.077 |
| 200 | 1.032 | 1.037 | 1.040 | 1.043 | 1.045 | 1.048 | 1.050 | 1.053 | 1.057 | 1.060 | 1.063 | 1.065 | 1.067 |
| 210 | 1.022 | 1.027 | 1.030 | 1.033 | 1.035 | 1.038 | 1.040 | 1.043 | 1.047 | 1.050 | 1.053 | 1.055 | 1.057 |

**Example 2.**—What is the factor of evaporation when the feedwater temperature is 122° F. and the gauge pressure 72?

Solution.—In the table, under the column headed 70 and opposite 120 in the left-hand column is found 1.128; in column headed 80 and opposite 120 is found 1.131; difference is .003. In the same vertical columns and opposite 130 are found 1.117 and 1.120; difference is .003, same as before. Hence, for an increase of 10 lb. in gauge reading, there is an increase of .003 in the factor of evaporation, or an increase of .0003 for 1 lb. and of .0003 × 2 = .0006 for 2 lb. Therefore, for a feedwater temperature of 120° and 72 lb. pressure, the factor of evaporation is 1.128 + .0006 = 1.1286. The difference between the numbers opposite 120 and 130 in the two columns headed 70 and 80, respectively, is 1.128 − 1.117 = .011, and 1.31 − 1.120 = .011, showing that, for an increase of temperature in the feedwater of 10°, there is a decrease in the factor of .011 and for 1° a decrease of .0011, or for 2° of .0022. Hence, the value of the factor for a temperature of 122° and a gauge pressure of 72 lb. is 1.1286 − .0022 = 1.126.

**Boiler Efficiency.**—The efficiency of a boiler may be defined as the ratio of the heat utilized in evaporating water to the total heat supplied by the fuel. The efficiency thus calculated is really the combined efficiency of the furnace and boiler, as it is not easily possible to determine separately the efficiency of each.

The amount of heat supplied is determined by first accurately weighing the fuel used during the test and deducting all the ash and unconsumed portions. This weight, in pounds, is multiplied by the total heat of combustion of 1 lb. of the fuel, as determined by an analysis, the product being the total number of heat units supplied during the test under the assumption that combustion was perfect. The heat usefully expended in evaporating water is obtained by first weighing the feedwater and correcting this weight according to the quality of the steam; the corrected weight is then multiplied by the number of heat units required to change water at the temperature of the feed into steam at the observed pressure. The efficiency of the boiler, expressed as a per cent., may be found by the formula

$$E = \frac{A}{B},$$

in which

$E$ = efficiency of boiler;
$A$ = heat utilized in evaporating water;
$B$ = total heat supplied by fuel.

**Example.**—A boiler trial shows a useful expenditure of 186,429,030 B. T. U. and a total supply of 270,187,000 B. T. U. What is the efficiency of the boiler?

Solution.—Applying the formula,

$$E = \frac{186,429,030}{270,187,000} = .69 = 69\%$$

**Standard Code.**—For elaborate boiler trials, the standard code recommended by the American Society of Mechanical Engineers should be used.

## BOILER MANAGEMENT

### FILLING BOILERS

**Preparation for Filling Boiler.**—Before starting the flow of water into the boiler, the manhole plates or handhole plates that were removed preparatory to cleaning and overhauling must be replaced, and the blow-off valve must be closed. The gaskets, and also the surfaces with which they come in contact, should be examined to see that they are in good condition. It is customary to place a mixture of cylinder oil and graphite on the outer surface of each gasket, so that it may be removed without tearing. It is important that the manhole plates and handhole plates be properly replaced and secured in order to prevent leakage.

**Height of Water.**—In some cases the water can flow in and fill the boiler to the required height by means of the pressure that exists in the main supply pipe. In other cases, it may be necessary to use a hose or to fill the boiler with a steam pump or a hand pump. The boiler should be filled until the water shows half way up in the gauge glass.

**Escape of Air.**—While filling a boiler it is necessary to make provision for the escape of the contained air, as otherwise the pressure caused by the compression of the air may prevent the boiler from being filled to the proper height.

Most boilers have some valve that can be used for this purpose; a gauge-cock may be left open until water issues therefrom, when it may be closed. Sometimes the manhole plate, if the manhole is on top, is left off while filling a boiler.

## MANAGEMENT OF FIRES WHEN STARTING

**Precautions in Starting.**—After the boiler has been filled and before starting the fire, the attendant should see that the water column and connections are perfectly clear and free, that is, that the valves in the connections and the gauge-glass valves are open so that the water level may show in the glass; he should also see that the gauge-cocks are in good working order and should open the top cock or the safety valve; he should take care that the stress on the stop-valve spindle is relieved by just unscrewing the valve from the seat without actually opening it. He should make sure that the pump, or injector, or whatever device is used to feed the boiler, is in good working order, and ready to start when required.

**Starting the Fires.**—It is customary to cover the grates with a layer of coal first, and then to add the wood, among which may be thrown oily waste or other combustible material that may be at hand. To start the fire, light the waste or other easily ignited material and open the damper and ashpit doors to produce draft. Then close the furnace door. After the wood has started to burn well, spread it evenly over the grate and add a fine sprinkling of coal, until this in turn begins to glow, when more coal may be added and the fire occasionally leveled until the proper thickness of fuel has been obtained. Should the chimney refuse to draw, the draft can generally be started by building a small fire in the base of the chimney.

**Value of Slow Fires.**—When getting up steam, the fire should not be forced but, instead, should be allowed to burn up gradually. By forcing the fire, the plates or tubes that are nearest the fire suffer extreme expansion, while those parts that are remote from the fire are still cold; under such conditions the seams and rivets, and also the tube ends, which are expanded into the tube plates, are liable to be severely strained, and, possibly, permanently injured. It is not desirable to raise steam in any boiler, except in steam fire-engines, in less than from 2 to 4 hr., according to the size, from the time the fire is first started. When steam begins to issue from the opened top gauge-cock or the raised safety valve, as the case may be, the cock or the valve may be closed and the pressure still allowed to rise slowly until the desired pressure has been reached.

**Trying the Fittings.**—After the pressure at which the boiler is to run has been reached, and before cutting it into service, all the valves and cocks should be tried. The safety valve should be raised and its action noted; the water column should be blown out and the gauge-cocks tested; the feeding apparatus should be tried; and it should be noted particularly whether the check-valves seat properly and the valve in the feedpipe is open. All the accessible parts should be examined for leaks.

## CONNECTING BOILERS

**Cutting Boiler Into Service.**—Cutting a boiler into service is accomplished by opening the stop-valve, thus permitting the steam to flow to the engine or other destination. The stop-valve should be opened very slowly to prevent a too sudden change in the temperature and consequent expansion of the piping through which the steam flows, and also to prevent water hammer. The steampipe drain should be kept open until the pipe is thoroughly warmed up. In large plants with many boilers and long steam mains, it takes several hours to warm these pipes thoroughly by the slow circulation of the steam, but the main stop-valve should not be fully opened until these pipes are warm.

**Connecting Boilers to Main.**—Before connecting the different boilers of a battery to the same steam main, the precaution of equalizing the pressures in the different boilers must be observed in order to prevent a sudden rush of steam from one boiler to another. All the pressures should be within about 2 lb. before an attempt is made to connect the boilers.

**Changing Over.**—In plants where there are duplicate sets of boilers, one set being in operation while the other is undergoing repairs, overhauling, and cleaning, the method of *changing over*, or connecting, is as follows: Start the fires and raise steam in the boilers that are to be cut into service. Allow the pressure to rise in all to within 5 lb. of that which is in the boilers in operation. All arrangements before changing over should be made with a view of getting all the heat that can be obtained from the fires in the boilers that are to be cut

out. This can be accomplished by running until the fires have given up all their available heat for making steam, as indicated by the gradual fall in pressure when the dampers are wide open, and then making the change. While the fires in one set of boilers are burning low and the pressure is falling, the pressure in the boilers to be cut in is gradually rising and meeting, so to speak, the falling pressure of the set in operation. When the difference of 5 lb. is reached, change over. A man should be stationed at each stop-valve, and while one is being opened the other should be closed; the engine will continue running uninterruptedly while the change is being made.

## EQUALIZING THE FEED

When the boilers of a battery have been cut into service and hence are all connected together through the steam main, the regulation and equalization of the feedwater becomes an important factor. Each boiler has its own check-valve and feed stop-valve, and generally all the boilers are supplied from one pump, which is running constantly. The quantity of water admitted to each boiler is regulated by its feed stop-valve. When the water gets low in any boiler the feed stop-valve should be opened wider, while at the same time the feed stop-valves on one or more of the other boilers in operation may be closed partly and thus divert the feedwater to the one most requiring it. Some boiler plants have check-valves with an adjustable lift; in that case the feed is equalized by adjusting the lifts of the check-valves, the stop-valves being left wide open while running. It will be understood from the foregoing that the object in view is the maintaining of an equal water level in all the boilers through the manipulation of the feed stop-valves or check-valves. A boiler that is not doing its legitimate share in generating steam may be known by the fact that the feed stop-valve or check-valve on that boiler will be nearly, if not entirely, closed most of the time.

## FIRING WITH SOLID FUEL

The safe and economical operation of steam boilers calls for careful and intelligent management. The fires should be kept in such condition as to maintain the desired pressure and to burn the fuel with economy. Different fuels require different handling and hence only general rules can be given; much will depend on the skill and judgment of the attendant, who must himself discover in each case by actual trial the best method to pursue. The fires must be cleaned at intervals; the time and method of cleaning depend on the nature of the fuel and the rapidity with which it is being consumed, the style of grate in use, and the construction of the furnace.

**Cleaning of Fires.**—There are two methods employed in cleaning the fires: first, that of cleaning the front half and then the rear half; second, that of cleaning one side of the fire and then the other side. In the first method, previous to cleaning, green fuel is thrown on and allowed to burn partly until it glows over the entire surface. The new and glowing fuel is then pushed to the back of the furnace with a hoe, leaving nothing on the front half of the grate but the ashes and clinkers, which are then pulled out, leaving the front end of the grate entirely bare. The new fire, which was pushed back, is drawn forwards and spread over the bare half of the grate. The ashes and clinkers that are on the rear half of the grate are then pulled over the top of the front half of the fire and out through the furnace door; this leaves the rear half of the grate bare, which must be covered by pushing back some of the new front fire. The clean fire having been spread evenly, some new fuel must be spread over the entire surface.

The second method is substantially the same in principle, but the fire is pushed to one side instead of to one end of the furnace. The condition of the fires themselves and the nature of the service of the plant will determine just how often and at what time the cleaning of fires should take place. In general, the fires in stationary boilers require cleaning at intervals of from 8 to 12 hr. Fires require cleaning more often when forced draft is used than when working with natural draft.

Rapidity in cleaning fires is of great importance, as during the operation a large volume of cold air enters the furnace and chills the metallic surfaces with which it comes in contact; consequently, the boiler is damaged, however slightly. It is the greatest advantage of shaking grates that they allow the fire to be cleaned without opening the furnace door; the inrush of cold air and consequent chilling of the plates, etc. is thus avoided.

Before starting to clean fires, the steam pressure and the water level should be run up as high as is safe and the feed should be shut off in order to reduce

the loss in pressure while cleaning. The condition of the fire during cleaning and the opening of the furnace doors cause the pressure to drop quite rapidly, but the rapidity and the amount of drop will be reduced by taking the precautions mentioned and cleaning quickly.

The amount of drop in pressure while cleaning fires depends on several conditions. For example, with a boiler that has a small steam space and, in addition, is, too small for the work required of it without forcing, it is to be expected that the drop in pressure will be much more than if the reverse conditions exist. Furthermore, it may be necessary to clean fires while steam is being drawn from the boiler, instead of being able to clean at a time when the engine is stopped. In that case a greater drop must be expected than when cleaning while no steam is being drawn from the boiler. It is advisable when possible to do the cleaning at a time when no steam is being drawn from the boiler or when the demand for steam is light.

## UNIFORM STEAM PRESSURE

**Desirability of Uniform Pressure.**—The attendant should aim to carry the pressure in the boiler as uniform as possible. A steady steam pressure and a steady water level are conducive to economy in the use of a fuel because, with these conditions, in a properly designed plant there will be a fairly steady temperature in the furnace, which, under normal conditions, is sufficiently high to insure a thorough ignition of the volatile matter in the coal. With a constant demand for steam, a fluctuation in the steam pressure is caused by a change in the furnace temperature, assuming the feedwater supply to be constant, and whenever the steam pressure is down, the furnace temperature is low at the same time. In consequence of this, large quantities of the volatile matter in the coal often escape unconsumed and cause a serious loss of heat. Furthermore, with a steady steam pressure the stresses on the boiler are constant, and hence the life of the boiler will be increased and repair bills will be smaller than otherwise.

**Maintenance of Uniform Pressure.**—During the period of time between the cleaning of the fires, the pressure may be carried nearly uniform by manipulating the feed apparatus so that just the necessary amount of water constantly enters the boiler. Intermittent feeding is practiced under certain local conditions, as, for example, where there is an injector or a pump that is so large that it is impossible to run it continuously without increasing the height of the water level. In such a case, the feeding must be stopped just before firing, and is not resumed until the new fire begins to make steam, as indicated by the rise of pressure on the gauge. If the pressure tends to rise above the standard or normal the dampers must be partly closed and the quantity of feed increased, assuming in this case that no damper regulator is fitted and that, hence, the damper is regulated by hand. A damper regulator, systematic firing, and proper feeding are essential for carrying a practically uniform pressure. Should the pressure continue to rise, more green fuel must be thrown on, the damper closed, the feed increased, and only as a last resort should the furnace door be opened.

A uniform steam pressure cannot be kept without proper firing. To maintain such a pressure the following directions should be observed: Keep the fire uniformly thick; allow no air holes in the bed of fuel; fire evenly and regularly; be careful not to fire too much at a time; keep the fire free from ashes and clinkers; and do not neglect the sides and corners while keeping the center clean. Do not, however, clean the fires oftener than is necessary. Keep the ash-pit clear.

**Keeping Water Level Constant.**—In connection with the maintenance of a constant water level, the following instructions should be followed: On starting to work, remember that the first duty of the fireman is to examine the water level. Try the gauge-cocks, as the gauge glass is not always reliable. If there is a battery of boilers, try the gauge-cocks on each boiler.

## PRIMING AND FOAMING

**Priming.**—The phenomenon called *priming* is analogous to boiling over; the water is carried into the steam pipes and thence to the engine, where considerable damage is liable to take place if the trouble is not checked in time. There are several causes for priming, the most common ones of which are: insufficient boiler power, defective design of boiler, water level carried too high, irregular firing, and sudden opening of stop-valves.

When the boiler power is insufficient, the best remedy is to increase the boiler plant; the next best thing to do is to put in a separator, which, obviously,

will only prevent the entrained water from reaching the engine, and will not stop the priming.

Defective design of a boiler generally consists of a steam space that is too small or a bad arrangement of the tubes, which may be spaced so close in an effort to obtain a large heating surface as to interfere seriously with the circulation. In horizontal return-tubular boilers, a sufficiently large steam space can be obtained by the addition of a steam drum; sometimes the top row of tubes can be taken out to advantage, which permits a lower water level. Defective circulation in horizontal fire-tube boilers is difficult to detect and to remedy; if it is due to a too close spacing of the tubes, a marked betterment may be effected by the removal of one or two vertical rows of tubes. The remedy for a water level that is too high is to carry the water at a lower level.

**Evidences of Priming.**—Priming manifests itself first by a peculiar clicking sound in the cylinder of the engine, due to water thrown against the heads. In cases of very violent priming, the water will suddenly rise several inches in the gauge glass, thus showing more water in the boiler than there really is. When priming takes place, it can be checked temporarily as follows: Close the damper, and thereby check the fires until the water is quiet; the engine stop-valve should also be partly closed to check the inrush of water. Observe whether the water drops in the gauge glass, and then, if more feed is needed, increase the feed. To prevent damage to the engine, open the cylinder drains. Regular and even firing tends to prevent priming.

**Foaming.**—The phenomenon called *foaming* is not the same as priming, though frequently considered so. Foaming is the result of dirty or greasy water in the boiler; the water foams and froths at the surface, but does not lift. A boiler may prime and foam simultaneously, but a foaming boiler does not always prime. Foaming while taking place is visible in the gauge glass and is best remedied by using the surface blow-off. If no surface blow-off is fitted, the bottom blow-off may be used in order to get rid of the dirty water. Like priming, foaming will cause a wrong level to be shown, and hence the first thing to do in case of foaming is to quiet the water by checking the outrush of steam, either by slowing the engine down or by checking the fire, or by both.

## SHUTTING DOWN AND STARTING UP

**Preparations for Shutting Down.**—Before shutting down for the night it is advisable to fill the boiler to the top of the glass, so as to be sure to have sufficient water to start with in the morning. The presence of possible leaks through the valves, tube ends, or seams necessitates this course of action. Even if no leaks exist, it is good practice to do this, if for no other reason than to admit of blowing out a portion before raising steam in the morning. All the gauge-cocks should be tried and the water column should be blown out to insure their being free and clear.

**Banking of Fires.**—The fires may be banked at such a time that there will be about enough steam to finish the day's run, thus shutting down under a reduced pressure with only a remote possibility of its rising again through the night. If the fires are properly banked and the steam worked off while the feed is on, it will be remotely possible for the pressure to rise during the night to a dangerous extent. To bank the fires they should be shoved to the back of the grate and well covered with green fuel, leaving the front part of the grate bare, thus preventing any possibility of the banked fire burning up through the night.

**Closing Valves and Damper.**—The steam stop-valve, feed stop-valve, whistle valve, and other steam valves should be closed; the valves at the top and bottom of the gauge glass also should be shut off to prevent loss of water, etc. in case the glass break during the night. If there is a damper regulator, it should be so arranged that the damper may be left closed, but not quite tight, because a small opening must be left to permit the collecting gases from the banked fire to escape up the chimney; otherwise, there is danger that the gas will ignite and cause an explosion. It is very important to take this precaution and also to make a mark by means of which the distance the damper is open can be ascertained at a glance. In fact, a damper should be so made that when shut to the full extent of its travel there will be still sufficient space around it to allow the gas to escape. The damper regulator should be rendered positively inoperative in any manner permitted by its design so that when closed it will remain in that position until connected properly by the attendant in the morning.

**Starting the Fires.**—On entering the boiler room in the morning, the quantity of water in the boiler should first be noted. The gauge glass and the

gauge-cocks should be tried and the water level determined. After it has been found that the water is not too low, the banked fires may be pulled down and spread over the grates and allowed to burn up slowly, the damper regulator, if one is fitted, in the meantime having been connected.

**Blowing Down.**—While the fires are burning up and before the pressure begins to rise, the blow-off cock or valve should be opened and the boiler blown down; that is, a small quantity of the water should be blown out. This should be done every morning, so that any impurities in mechanical suspension in the water that settled during the night may be removed. Great care should be exercised while doing this so that too much water is not blown out; from 3 to 4 in. as shown by the gauge glass, is sufficient. Under no circumstances should the attendant leave the blow-off while it is open. Disaster to the boiler is liable to follow a disregard of this injunction. Next, all the valves, except the stop-valve, which were shut the night before should be opened and tried to see that they are free and in good working order.

## CARE OF BOILERS

**Safety Valves.**—Great care should be exercised to see that the safety valves are ample in size and in working order. Overloading or neglect frequently lead to the most disastrous results. Safety valves should be tried at least once every day, to see that they act freely.

**Pressure Gauge.**—The steam gauge should stand at zero when the pressure is off, and it should show the same pressure as that at which the safety valve is set when that is blowing off. If the pressures do not agree, the gauge should be compared with one known to be correct.

**Water Level.**—The first duty of an engineer before starting, or at the beginning of his watch, is to see that the water is at the proper height. He should not rely on glass gauges, floats, or water alarms, but try the gauge-cocks. If they do not agree with the water gauge, the cause should be learned and the fault corrected.

**Gauge-Cocks and Water Gauges.**—All gauge-cocks and water gauges must be kept clean. Water gauges should be blown out frequently, and the glasses and passages to them kept clean. The Manchester, England, Boiler Association attributes more accidents to inattention to water gauges than to all other causes put together.

**Feed-Pump or Injector.**—The feed-pump or injector should be kept in perfect order, and be of ample size. No make of pump can be expected to be continuously reliable without regular and careful attention. It is always safe to have two means of feeding a boiler. Check-valves and self-acting feed-valves should be frequently examined and cleaned. The attendant should satisfy himself frequently that the valve is acting when the feed-pump is at work.

**Low Water.**—In case of low water, immediately cover the fire with ashes (wet if possible) or any earth that may be at hand. If nothing else is handy, use fresh coal. Draw fire as soon as it can be done without increasing the heat. Neither turn on the feed, start nor stop engine, nor lift safety valve until fires are out and the boiler cooled down.

**Blisters and Cracks.**—Blisters and cracks are liable to occur in the best plate iron. When the first indication appears, there must be no delay in having the fault carefully examined and properly cared for.

**Fusible Plugs.**—When used, fusible plugs must be examined when the boiler is cleaned, and carefully scraped clean on both the water and fire sides, or they are liable not to act.

**Firing.**—Fire evenly and regularly, a little at a time. Moderately thick fires are most economical, but thin firing must be used where the draft is poor. Take care to keep grates evenly covered, and allow no air holes in the fire. Do not clean fires oftener than necessary. With bituminous coal, a coking fire, i. e., firing in front and shoving back when coked, gives best results, if properly managed.

**Cleaning.**—All heating surfaces must be kept clean outside and in, or there will be a serious waste of fuel. The frequency of cleaning will depend on the nature of fuel and water. When a new feedwater supply is introduced, its effect on the boiler should be closely observed, as this new supply may be either an advantage or a detriment as compared with the working of the boiler previous to its introduction. As a rule, never allow over $\frac{1}{16}$ in. of scale or soot to collect on surfaces between cleanings. Handholes should be frequently removed and surfaces examined, particularly in the case of a new boiler, until proper intervals have been established by experience.

The exterior of tubes can be kept clean by the use of blowing pipe and hose through openings provided for that purpose. When using smoky fuel, it is best to occasionally brush the surfaces when steam is off.

**Hot Feedwater.**—Cold water should never be fed into any boiler when it can be avoided, but when necessary it should be caused to mix with the heated water before coming in contact with any portion of the boiler.

**Foaming.**—When foaming occurs in a boiler, checking the outflow of steam will usually stop it. If caused by dirty water, blowing down and pumping up will generally cure it. In cases of violent foaming, the draft and fires should be checked.

**Air Leaks.**—Be sure that all openings for admission of air to boiler or flues, except through the fire, are carefully stopped; this is frequently an unsuspected cause of serious waste of fuel.

**Blowing Off.**—If feedwater is muddy or salt, blow off a portion frequently, according to condition of water. Empty the boiler every week or two, and fill up afresh. When surface blow cocks are used, they should be often opened for a few minutes at a time. Make sure no water is escaping from the blow-off cock when it is supposed to be closed. Blow-off cocks and check-valves should be examined every time the boiler is cleaned. Never empty the boiler while the brickwork is hot.

**Leaks.**—When leaks are discovered, they should be repaired as soon as possible.

**Filling Up.**—Never pump cold water into a hot boiler. Many times leaks, and, in shell boilers, serious weaknesses, and sometimes explosions are the result of such an action.

**Dampness.**—Take care that no water comes in contact with the exterior of the boiler, as it tends to corrode and weaken it. Beware of all dampness in seatings and coverings.

**Galvanic Action.**—Examine frequently parts in contact with copper or brass, where water is present, for signs of corrosion. If water is salt or acid, some metallic zinc placed in the boiler will usually prevent corrosion, but it will need attention and renewal from time to time.

**Rapid Firing.**—In boilers with thick plates or seams exposed to the fire, steam should be raised slowly, and rapid or intense firing avoided. With thin water tubes, however, and adequate water circulation, no damage can come from that cause.

**Standing Unused.**—If a boiler is not required for some time, empty and dry it thoroughly. If this is impracticable, fill it quite full of water, and put in a quantity of common washing soda. External parts exposed to dampness should receive a coating of linseed oil.

**Repair of Coverings.**—All coverings should be looked after at least once a year, given necessary repairs, refitted to the pipe, and the spaces due to shrinkage taken up. Little can be expected from the best non-conductors if they are allowed to become saturated with water, or if air-currents are permitted to circulate between them and the pipe.

**General Cleanliness.**—All things about the boiler room should be kept clean and in good order; negligence tends to waste and decay.

---

# BOILER INSPECTION

## NATURE OF INSPECTION

The inspection of a boiler usually consists in an external examination of the complete structure, and of the setting if the boiler is externally fired, and an internal inspection. The examination of the boiler consists of an ocular inspection for visible defects, and a *hammer test* or sounding for hidden defects of plates, stays, braces, and other boiler parts. The hammer test is made by tapping the suspected parts with a light hammer and judging the existence and extent of defects from the sound produced by the blow. If the examination discloses marked wear and tear, a series of calculations is often required to find the safe pressure that may be allowed on the worn parts, using such formulas or rules as laws, ordinances, and regulations may prescribe. In the absence of officially prescribed formulas and rules, the inspector should use such rules as he deems in best accordance with good practice. The inspection is usually, but not always, completed by a so-called *hydrostatic test*, which is generally prescribed by official regulations.

## EXTERNAL INSPECTION

**Preparation.**—Before a boiler that has been in use can be inspected, it must be blown out and must be allowed to cool off. As soon as the water has been removed, the manhole covers, handhole covers, and washout plugs should be taken out and all loose mud and scale washed out with a hose. If the boiler is externally fired, the tubes must be swept and the furnace, the ash-pit, the smokebox, and the space back of the bridge wall must be cleaned out. Any removable insulating covering that prevents the inspector from having free access to the exterior of the boiler must be removed to the extent deemed necessary by him; it may even be necessary to take down some of the bricks of the setting.

**Inspection of Externally Fired Boilers.**—In the inspection of an externally fired fire-tube or flue boiler, the exterior is first examined. The seams are gone over inch by inch; the rivet heads and calking edges of the plates are carefully scrutinized for evidence of leaks; and possible cracks are looked for between the rivet heads, especially in the girth seams and on the under side of the boiler. The plates must also be examined for corrosion, bulges, blisters, and cracks. The heads are inspected for cracks between the tubes or flues, cracks in the flanges, leaky tubes, and leaks in the seams. The condition of the firebrick lining of the furnace and bridge and the top of the rear combustion chamber is noted while making the exterior examination of the underside of the boiler. Every defect that is found should be clearly marked. Attention must also be paid to the condition of the grate bars and their supports.

**Inspection of Internally Fired Boilers.**—The inspection of the shell and heads must be followed by examination of the fire-box or furnace tubes or flues, and of the combustion chambers if these are fitted inside the boiler. In fire-boxes, special attention must be paid to the crown sheet. The ends of the staybolts require close examination; if such ends are provided with nuts, these must be examined, as they are liable to loosen and are also liable to be burned off in time. Each staybolt should be tested for breakage, which is done by holding a sledge against the outside end of the staybolt and striking the inner, or fire-box, end with a light hammer; in making this test on the boilers of locomotives it is customary, when practical, to subject the boiler to an internal air pressure of from 40 to 50 lb. per sq. in. The internal pressure, by bulging the sheets, separates the ends of a broken staybolt, which renders it comparatively easy to find them by the hammer test.

**Inspection of New Boilers.**—As made in boiler shops, the external inspection of new boilers, whether they are internally or externally fired, and whether they are of the water-tube or the fire-tube type, usually consists in a thorough examination for visible defects and testing under water pressure to locate leaks. If a new boiler subject to official inspection during construction successfully passes such a hydrostatic test as the regulations prescribe, it will usually be permitted the working pressure it was designed for, the design having been approved officially before construction. The working pressure will be reduced, however, if the inspection discloses poor workmanship.

In the external inspection of water-tube boilers that have been in use, the tubes that are exposed directly to the heat of the fire must be particularly well examined for evidence of overheating. The plugs or handholes placed in headers to permit the insertion of the tubes and the cleaning of them are inspected for leakage, and the headers are inspected for cracks. Steam drums and mud-drums should be examined as carefully and for the same defects as the shells of externally fired fire-tube boilers. The fire-brick lining of the furnace, and the interior of the brick setting in general, as well as the baffle plates controlling the direction of flow of the gases of combustion, must be examined for cracks and any other defects. The external inspection of the setting can usually be made very rapidly, as everything is in plain sight.

## INTERNAL INSPECTION

**Preparation.**—Before the internal inspection is begun all loose mud should be washed out with a hose. In a horizontal return-tubular boiler and flue boiler, the shell plates and heads should be examined for corrosion and pitting; if the boiler has longitudinal lap seams, these should be inspected at the inside calking edge for incipient grooving and cracks. All seams should be examined for cracks between the rivet holes. Obviously, if the boiler is scaled to an appreciable degree, the scale must be removed before inspection. The tubes or flues should be examined for pitting, as well as for uniform corrosion. All braces should be inspected by sounding them with a hammer, and if they are attached by cotter pins, it should be seen to that these are firmly in place.

All defects found should be marked; it is good practice to make a memorandum of them as well. If any of the bracing seems to have worn considerably, it should be measured at the smallest part in order that the safe working pressure thereon may be calculated afterwards. To determine to what thickness a plate attacked by uniform corrosion has been reduced the inspector will have one or more holes drilled through the plate in the worn part to enable him to measure the thickness. These holes are afterwards plugged, generally by tapping out and then screwing in a plug.

**Inspection of Locomotive-Type Boilers.**—In internally fired boilers of the fire-box and locomotive type, particular attention must be paid to the crown bars, crown bolts, and sling stays; in boilers having the crown sheet stayed by radial staybolts, special attention is also paid to these. As a general rule, the inspector can make only an ocular inspection of most of them, as they are beyond his reach; where the outer sheets of the firebox contain inspection or washout holes above the level of the crown sheet, a lighted candle tied or otherwise fastened to a stick can usually be introduced through these holes from the outside by a helper. In inspecting above the crown sheet, the inspector should look for mud between the crown sheet and crown bars and sight over the top of the bars to see if any have been bent. As the inspector can reach from the inside of the boiler only a few of the staybolts staying the sides of the firebox, he must rely on the hammer test applied from the inside of the furnace for finding broken staybolts.

**Flues and Combustion Chambers.**—In boilers having circular furnace flues and internal combustion chambers, the top of the furnace flues must be carefully inspected for deposits of grease and scale, which are especially liable to be found if the feedwater is obtained from a surface condenser. Even a light deposit of grease on the furnace flue is liable to lead to overheating and subsequent collapse of the top. The tops of the combustion chambers, together with their supports, are usually easily inspected, there being ample space to reach every part.

**Inspection of Vertical Boilers.**—Vertical boilers as a general rule, except in the largest sizes, have no manhole to admit a person to the inside, and such internal inspection as is possible must be made through the handholes. Defects to be looked for are pitting and uniform corrosion of the shell and tubes near the usual water-line, and cracks in the heads between the tubes, the lower head being especially liable to show this injury.

## INSPECTION OF FITTINGS

**Inspection of Safety Valve.**—The safety valve requires very careful inspection. If this valve is known to leak, it should be reseated and reground before the hydrostatic test is made. After a boiler passes the hydrostatic test, the clamp locking the safety valve is removed, and by running the pressure up once more, the point at which the safety valve opens can be noted by watching the steam gauge, which is supposed to have been tested and corrected. If the safety valve does not open at the working pressure allowed or opens too soon, it is readjusted. If the safety valve is locked by a seal, as is often required by official regulations, the seal is applied after adjustment of the valve.

**Testing of Steam Gauge.**—The steam gauge should be tested before the hydrostatic test and at each inspection with a so-called boiler inspector's testing outfit. If the gauge under test is more than 5% incorrect most inspectors will condemn it although some will condemn gauges showing a much smaller error. In most cases the gauge can be repaired at small expense by the makers.

**Inspection of Water Gauge and Blow-off.**—The connections of water column and water-gauge glasses require examination in order to see that they are clear throughout their whole length. The blow-off pipe also requires examination in order to see that it is clear.

## SELECTION OF BOILERS

**General Requirements.**—When choosing a boiler, the facts to be kept in mind are:

1. The grate surface must be sufficient to burn the maximum quantity of coal expected to be used at any time, taking into consideration the available draft, the quality of coal, its percentage of ash, whether or not the ash tends to run into clinker, and the facilities, such as shaking grates, for getting rid of the ash or clinker.

2. The furnace must be adapted to burn the particular kind of coal used.

3. The heating surface must be sufficient to absorb so much of the heat generated that the gases escaping into the chimney will be not over 450° F. with anthracite, and 550° F. with bituminous coal.

4. The gas passages must be so designed and arranged as to compel the gas to traverse at a uniform rate the whole of the heating surface, being not so large at any point as to allow the gas to find a path of least resistance, or short-circuiting, or, on the other hand, so contracted at any point as to cause an obstruction to the draft.

When these elements are found in any boiler—and they may be found in boilers of many of the common types—the relative merits of the different types may be considered with reference to their danger of explosion; their probable durability; the character and extent of repairs that may be needed from time to time, and the difficulty, delay, and expense that these may entail; the accessibility of every part of the boiler to inspection, internal and external; the facility for removal of mud and scale from every portion of the inner surface, and of dust and soot from the exterior; the water and steam capacity; the steadiness of water level; and the arrangements for securing dry steam.

**Liability to Explosion.**—All boilers may be exploded by overpressure, such as might be caused by the combination of an inattentive fireman and an inoperative safety valve, or by corrosion weakening the boiler to such an extent as to make it unable to resist the regular working pressure; but some boilers are much more liable to explosion than others. When selecting a boiler, it is well to see whether or not it has any of the features that are known to be dangerous.

The plain cylinder boiler is liable to explosion from strains induced by its method of suspension, and by changes of temperature. Alternate expansion and contraction may produce a line of weakness in one of the rings, which may finally cause an explosion. A boiler should be so suspended that all its parts are free to change their position under changes of temperature without straining any part. The circulation of water in the boiler should be sufficient to keep all parts at nearly the same temperature. Cold feedwater should not come in contact with the shell, as this will cause contraction and strain.

The horizontal tubular boiler, and all externally fired shell boilers, are liable to explosion from overheating of the shell, due to accumulation of mud, scale, or grease, on the portion of the shell lying directly over the fire, to a double thickness of iron with rivets, together with some scale, over the fire, or to low water uncovering and exposing an unriveted part of the shell directly to the hot gases.

Vertical tubular boilers are liable to explosion from deposit of mud, scale, or grease, upon the lower tube-sheet, and from low water allowing the upper part of the tubes to get hot and cease to act as stays to the upper tube-sheet.

Locomotive boilers may explode from deposits on the crown sheet, from low water exposing the dry crown sheet to the hot gases, and from corrosion of the staybolts.

Double-cylinder boilers, such as the French elephant boiler, and the boilers used at some American blast furnaces, have exploded on account of the formation of a steam pocket on the upper portion of the lower drum, the steam being prevented from escaping from out of the rings of the drum by the lap joint of the adjoining ring, thus making a layer of steam about $\frac{1}{4}$ in. thick against the shell, which was directly exposed to the hot gases. In the case of vertical or inclined tubes acting as stays to an upper sheet, the upper part of the tubes may become overheated in case of low water; also, when there are stayed sheets, the stays are liable to become corroded.

In addition to these features of design, all boilers are liable to explosion due to corrosion. Internal corrosion is usually due to acid feedwater, and all boilers are equally liable to it. External corrosion, however, is more liable to take place in some designs of boilers than others, and in some locations rather than others. If any portion of a boiler is in a cold and damp place, it is liable to rust out. For this reason the mud-drums of many modern forms of boilers are made of cast iron, which resists rusting better than either wrought iron or steel. If any part of a boiler, other than a part made of cast iron, is liable to be exposed to a cold and damp atmosphere, or covered with damp soot or ashes, or exposed to drip from rain or from leaky pipes, and especially if such part is hidden by brickwork or otherwise so that it cannot be seen, that part is an element of danger.

The causes of boiler explosions may be summarized as follows: (1) Bad materials; (2) bad workmanship; (3) bad water, which eats away the plates by internal corrosion; (4) water lying upon plates, bringing about external

corrosion; (5) overpressure; (6) safety valves sticking; (7) water getting too low; (8) excessive firing; (9) hot gases, acting on plates above water level; (10) choking of feedpipes; (11) insufficient provision for expansion and contraction; (12) insufficient steam room and too sudden a withdrawal of a large quantity of steam; (13) getting up steam, or knocking off a boiler too suddenly; (14) allowing wet ashes to lie in contact with plates. The probable causes suggest their several remedies.

**Durability.**—The question of durability is partly covered by that of danger of explosion, but it also is related to the question of incrustation and scale. The plates and tubes of a boiler may be destroyed by internal or external corrosion and by being burned out. It may be regarded as impossible to burn a plate or tube of iron or steel, no matter how high the temperature of the flame, provided one side of the metal is covered with water. However, if a steam pocket is formed, or if there is a layer of grease or hard scale, so that the water does not touch the metal, the plate or tube may be burned. In a water tube that is horizontal, or nearly so, and in which the circulation of water is defective, it is possible to form a mass of steam that will drive the water away from the metal, and thus allow the tube to burn out. When considering the probable durability of a boiler, it is necessary to consider the same things as when investigating the danger of explosion. There are, however, many chances of burning out a minor part of a boiler without serious danger, to one chance of a disastrous explosion. Thus the tubes of a water-tube boiler, if allowed to become thickly covered with scale, might be burned out again and again without causing any further destruction at any one time than the rupture of a single tube. A new type of boiler should be considered with regard to the likelihood of frequent small repairs being necessary, as well as with regard to its liability to complete destruction. The most important of these considerations are: The circulation through all parts of the boiler must be such that the water cannot be driven out of any tube or from any portion of a plate, so as to form a steam pocket exposed to high temperature; there must be proper facilities for removing the scale from every portion of the plates and tubes.

**Repairs.**—The questions of durability and of repairs are, in some respects, related to each other; the more infrequent and the less extensive the repairs, the greater the durability. The tubes of a boiler, where corroded or burnt out, may be replaced and made as good as new. The shell, when it springs a leak, may be patched, but is then likely to be far from as good as new. When the shell corrodes badly it must be replaced, and to replace the shell is the same as getting a new boiler. Herein is the advantage of the sectional water-tube boilers. The sections, or parts of a section, may be renewed easily, and made as good as new, while the shell, being far removed from the fire and easily kept dry externally, is not liable either to burning out or to external corrosion. When considering the merits of a new style of boiler, with reference to repairs, it may be asked what parts of the boiler are most likely to give out and need to be repaired or replaced? Are these repairs easily effected, how long will they require, and, after they are made, is the boiler as good as new?

**Facility for Removal of Scale and for Inspection.**—The matter of facility for the removal of scale and for inspection has already been discussed to some extent under the head of durability. Some early water-tube boilers had no facilities for the removal of scale, it being claimed that they did not need any, because their circulation was so rapid. If there is scale-forming material in the water it will be deposited when the water is evaporated, and no amount or kind of circulation will keep it from accumulating on every part of the boiler, and in every kind of tubes, vertical, horizontal, or inclined. The nearly vertical circulating tubes of a water-tube boiler, in which the circulation is nine times as fast as the average circulation in the inclined tubes, have been found nearly full of scale; that is, a 4-in. tube had an opening in it of less than 1 in. in diameter. This was due to carelessness in blowing off the boiler, or to exceptionally bad feedwater, or both.

**Water and Steam Capacity.**—It is claimed for some forms of boilers that they are better than others because they have a larger water or steam capacity. Great water capacity is useful where the demands for steam are extremely fluctuating, as in a rolling mill or a sugar refinery, where it is desirable to store up heat in the water in the boilers during the periods of the least demand to be given out during periods of greatest demand. Large water capacity is usually objectionable in boilers for factories, especially if they do not run at night and the boilers are cooled down, because there is a large quantity of water to be heated before starting each morning. If *rapid steaming*, or the ability

to get up steam quickly from cold water, or to raise the pressure quickly, is desired, large water capacity is a detriment.

The advantage of large steam capacity is usually overrated. It is useful to enable the steam to be drained from water before it escapes into the steam pipe, but the same result can be effected by means of a dry pipe, as in locomotive and marine practice, in which the steam space in the boiler is very small in proportion to the horsepower. Large steam space in the boiler is of no importance for storing energy or equalizing the pressure during the stroke of an engine. The water in the boiler is the place to store heat, and if the steam pipe leading to an engine is of such small capacity that it reduces the pressure, the remedy is a steam reservoir close to the engine or a large steam pipe.

To secure steadiness of water level requires either a large area of water surface, so that the level may be changed slowly by fluctuations in the demand for steam or in the delivery of the feed-pump, or else constant, and preferably automatic, regulation of the feedwater supply to suit the steam demand. A rapidly lowering water level is apt to expose dry sheets or tubes to the action of the hot gases, and thus be a source of danger. A rapidly rising level may, before it is seen by the fireman, cause water to be carried over into the steam pipe, and endanger the engine.

**Water Circulation.—**Positive and complete circulation of the water in a boiler is necessary to keep all parts of the boiler at a uniform temperature, and to prevent the adhesion of steam bubbles to the surface, which may cause overheating of the metal. It is claimed by some manufacturers that the extremely rapid circulation of water in their boilers tends to make them more economical than others. However, proof is lacking that increased rapidity of circulation of water beyond that usually found in any boiler will give increased

## RATIO OF HEATING SURFACE TO HORSEPOWER AND TO GRATE AREA

| Type of Boiler | Ratio = $\dfrac{\text{Heating Surface}}{\text{Horsepower}}$ | Ratio = $\dfrac{\text{Heating Surface}}{\text{Grate Area}}$ |
|---|---|---|
| Plain cylindrical...... | 6 to 10 | 12 to 15 |
| Flue.............. | 8 to 12 | 20 to 25 |
| Return-tubular....... | 14 to 18 | 25 to 35 |
| Vertical............. | 15 to 20 | 25 to 30 |
| Water-tube.......... | 10 to 12 | 35 to 40 |
| Locomotive.......... | 1 to 2 | 50 to 100 |

economy. It is known that increased rate of flow of air over radiating surfaces increases the amount of heat transmitted through the surface, but this is because by the increased circulation, cold air is continually brought into contact with the surface, making an increased difference of temperature on the two sides, which causes increased transmission. But by increasing the rapidity of circulation in a steam boiler, it is not possible to vary the difference of temperature to any appreciable extent, for the water and the steam in the boiler are at about the same temperature throughout. The ordinary or "Scotch" form of marine boiler shows an exception to the general rule of uniformity of temperature of water throughout the boiler, but the temperature above the level of the lower fire-tubes is practically uniform.

**Heating Surface.—**In the various types of boilers, there is a nearly constant ratio between the water-heating surface and the horsepower, and also between the heating surface and the grate area. These ratios are given in an accompanying table. If the heating surface of a boiler is known, the horsepower can be found roughly; thus, if a return-tubular boiler has a heating surface of 900 sq. ft., its horsepower lies between $900 \div 18 = 50$ H. P. and $900 \div 14 = 64.3$ H. P., say about 57 H. P.

The heating surface of a boiler is the portion of the surface exposed to the action of flames and hot gases. This includes, in the case of a multitubular boiler, the portions of the shell below the line of brickwork, the exposed heads of the shell, and the interior surface of the tubes. In the case of a water-tube boiler, the heating surface comprises the portion of the shell below the brickwork, the outer surface of the headers, and the outer surface of the tubes. In any given case, the heating surface may be calculated by the rules of mensuration.

The following example will show the method of calculating the heating surface of a return-tubular boiler:

EXAMPLE.—What is the heating surface of a horizontal return-tubular boiler that has the following dimensions: Diameter, 60 in.; length of tubes, 12 ft.; internal diameter of tubes, 3 in.; number of tubes, 82.

SOLUTION.—Assume that two-thirds of the shell is in contact with hot gases or flame, and two-thirds of the two heads are heating surface.

Circumference of shell is $60 \times 3.1416 = 188.496 = 188.5$ in., say.

Length of shell is $12 \times 12 = 144$ in.

Heating surface of shell is $188.5 \times 144 \times \frac{2}{3} = 18,096$ sq. in.

Circumference of tube is $3 \times 3.1416 = 9.425$ in., nearly.

Heating surface of tubes is $82 \times 144 \times 9.425 = 111,290.4$ sq. in.

Area of one head is $60^2 \times .7854 = 2,827.44$ sq. in.

Two-thirds area of both heads is $\frac{2}{3} \times 2 \times 2,827.44 = 3,769.92$ sq. in.

From the heads must be subtracted twice the area cut out by the tubes; this is $82 \times 3^2 \times .7854 \times 2 = 1,159.26$ sq. in.

Total heating surface in square feet is

$$\frac{18,096 + 111,290.4 + 3,769.92 - 1,159.26}{144} = 916.64 \text{ sq. ft.}$$

## PROBABLE MAXIMUM WORK OF A PLAIN CYLINDRICAL BOILER OF 120 SQ. FT. HEATING SURFACE AND 12 SQ. FT. GRATE SURFACE

| | 2 | 3 | 3.5 | 4 | 4.5 | 5 | 6 | 7 | 8 |
|---|---|---|---|---|---|---|---|---|---|
| Rate of driving; pounds of water evaporated per sq. ft. of heating surface per hour ....... | 2 | 3 | 3.5 | 4 | 4.5 | 5 | 6 | 7 | 8 |
| Total water evaporated by 120 sq. ft. heating surface per hour, pounds...... | 240.00 | 360.00 | 420.00 | 480.00 | 540.00 | 600.00 | 720.00 | 840.00 | 960.00 |
| Horsepower 34.5 lb. per hour = 1 H.P. | 6.96 | 10.43 | 12.17 | 13.91 | 15.65 | 17.39 | 20.87 | 24.35 | 27.83 |
| Pounds water evaporated per pound combustible . | 10.88 | 11.30 | 11.36 | 11.29 | 11.20 | 11.05 | 10.48 | 9.48 | 8.22 |
| Pounds combustible burned per hour..... | 22.10 | 31.90 | 37.00 | 42.50 | 48.20 | 54.30 | 68.70 | 88.60 | 116.80 |
| Pounds combustible per hour per square foot of grate . | 1.85 | 2.65 | 3.08 | 3.55 | 4.02 | 4.52 | 5.72 | 7.38 | 9.73 |
| Pounds combustible per hour per horse-power....... | 3.17 | 3.05 | 3.04 | 3.06 | 3.08 | 3.12 | 3.30 | 3.64 | 4.16 |

The figures in the last line show that the amount of fuel required for a given horsepower is nearly 37% greater when the rate of evaporation is 8 lb. than when it is 3.5 lb.

The figures in the foregoing table that represent the economy of fuel, viz., Pounds water evaporated per pound combustible and Pounds combustible per hour per horsepower, are what may be called maximum results, and they are the highest that are likely to be obtained with anthracite, with the most skillful firing and with every other condition most favorable. Unfavorable conditions, such as poor firing, scale on the inside of the heating surface, dust

or soot on the outside, imperfect protection of the top of the boiler from radiation, leaks of air through the brickwork, or leaks of water through the blow-off pipe, may greatly reduce these figures.

---

# CHIMNEYS

**Products of Combustion.**—The weight and volume of the various gases that enter into problems relating to combustion when measured at 32° F. and the average atmospheric pressure at sea level of approximately 14.7 lb. per sq. in., corresponding to a height of the mercurial barometer of 29.92 in. are given under the subject of Ventilation. To find the volume at any other temperature and pressure, the following formula is used,

$$v_1 = v_2 \frac{p_2 T_1}{p_1 T_2},$$

in which $v_2$ = volume corresponding to absolute pressure $p_2$ and absolute temperature $T_2$ (or $460 + t_2$);

$p_2$ = any given absolute pressure;

$v_1$ = volume at any other pressure $p_1$ and absolute temperature $T_1$ (or $460 + t_1$).

EXAMPLE.—What is the volume of 4 lb. of dry air at 75° F. and under an absolute pressure of 20 lb. per sq. in.?

SOLUTION.—From the table, it is found that 1 lb. of air, at 32° F. and 14.7 lb. per sq. in. absolute pressure, occupies 12.388 cu. ft., hence, under the same conditions, 4 lb. occupies $4 \times 12.388 = 49.552$ cu. ft. Substituting, in the formula, the values $v_2 = 49.552$, $p_2 = 14.7$ lb. per sq. in., $p_1 = 20$ lb. per sq. in., $t_1 = 75°$ F., we get     $v_1 = 49.552 \times \frac{14.7}{20} \times \frac{535}{492} = 39.6$ cu. ft.

Hitherto it has been considered that the fuel was burned in oxygen. When burning with air, the chemical reactions are the same, for the nitrogen in the air passes through the furnace unchanged. In calculations of temperature, however, account must be taken of the nitrogen, as it is heated by the combustion and therefore absorbs heat and causes the furnace to have a lower temperature than if oxygen alone were used.

The first table on page 447 gives the weights of air, water vapor, and saturated mixtures of air and water vapor at different temperatures, under the ordinary atmospheric pressure of 14.7 lb. per sq. in., or 29.92 in. of mercury.

EXAMPLE.—A coal whose heating value is 12,000 B. T. U. per lb., is burned with 20 lb. of air (not including water vapor) per lb. of coal. The relative humidity of the air is 90%, and its temperature is 92° F. How much heat is lost in the chimney gases on account of the moisture in the air, if the chimney gases escape at 512° F.?

SOLUTION.—From the table, it is found that 1 lb. of air will hold, when fully saturated, .03289 lb. of water vapor at 92° F.; hence, 20 lb. of air will hold 20 × .03289 = .6578 lb. of water vapor; at 90% relative humidity, it will hold .6578 × .90 = .59202 lb. water vapor.

The amount of heat absorbed in heating 1 lb. of water from 92° F. to 512° F. is: (a) From 92° to 212°, or through 120°, is 120 × 1 (specific heat of water) = 120 B. T. U.; (b) From 212° to 512°, or through 300°, is 300 × .48 (specific heat of superheated steam) = 144 B. T. U. The total absorption is 120 + 144 = 264 B. T. U. .59202 lb. water will absorb 264 × .59202 = 156.29 B. T. U. or $\frac{156.29 \times 100}{12,000} = 1.3\%$ of the heating value of the coal.

EXAMPLE.—How many cubic feet of dry air per pound of coal are used in the preceding example, if the air is at the mean atmospheric pressure of 14.7 lb. per sq. in.?

SOLUTION.—From the table, by calculation, it is found that 1 lb. of air at 32° and at the mean atmospheric pressure occupies $1 \div .0807 = 12.39$ cu. ft. At 92° it occupies $12.39 \times \frac{92 + 460}{492} = 13.9$ cu. ft.; 20 lb. will occupy $13.9 \times 20 = 278$ cu. ft.

EXAMPLE.—How many cubic feet of air must be delivered per minute by a fan, to drive 1,000 H. P. of boilers under the conditions of the preceding examples, if 4 lb. of coal is burned per H. P. per hr.?

SOLUTION.—     $\frac{4 \times 1,000 \times 278}{60} = 18,533$ cu. ft. per min.

## WEIGHT OF AIR, WATER VAPOR, AND SATURATED MIXTURES AT DIFFERENT TEMPERATURES

| Temperature Degrees F. | Weight of 1 Cu. Ft. of Dry Air at Different Temperatures Pound | Elastic Force of Water Vapor Inches of Mercury | Mixtures of Air Saturated With Vapor | | | | |

## OXYGEN AND AIR REQUIRED FOR THE COMBUSTION OF CARBON, HYDROGEN, ETC.

| Fuel | Chemical Reaction | Pounds $O$ per Pound Fuel | Pounds $N = 3.32 \times O$ | Air per Pound $= 4.32 \times O$ | Gaseous Product per Pound Fuel |
|---|---|---|---|---|---|
| Carbon to $CO_2$ | $C + 2O = CO_2$ | $2\frac{2}{3}$ | 8.85 | 11.52 | 12.52 |
| Carbon to $CO$ | $C + O = CO$ | $1\frac{1}{3}$ | 4.43 | 5.76 | 6.76 |
| Carbon monoxide to $CO_2$ | $CO + O = CO_2$ | $\frac{4}{7}$ | 1.90 | 2.47 | 6.76 |
| Hydrogen to $H_2O$ | $2H + O = H_2O$ | 8 | 26.56 | 34.56 | 35.56 |
| Marsh gas (methane), $CH_4$ to $CO_2$ and $H_2O$ | $CH_4 + 4O = CO_2 + 2H_2O$ | 4 | 13.28 | 17.28 | 18.28 |
| Sulphur to $SO_2$ | $S + 2O = SO_2$ | 1 | 3.33 | 4.32 | 5.32 |

The preceding table contains, in convenient form, the reactions involved in the combustion of various fuels, as explained more in detail before, as well as the weight of air, oxygen, and nitrogen, required to burn 1 lb. of the fuel,

and the weight of the products of combustion resulting therefrom. It is found, in practice, that if air is blown through a bed of hot anthracite or coke, and the resulting gases are analyzed, they always contain some carbon monoxide, showing imperfect combustion, unless they contain a considerable quantity of uncombined oxygen, or air. The excess of air required to effect complete combustion to carbon dioxide is usually not less than 50% of that theoretically necessary, so that about 17 lb. of air is required to insure the complete combustion of 1 lb. of carbon instead of 11.52 lb., the figure given in the table. It is probable, also, that more than 34.56 lb. of air is required to effect the combustion of each pound of hydrogen in a furnace, although, experimentally, one volume of oxygen and two volumes of hydrogen mixed together, or eight parts by weight of oxygen to one of hydrogen may be exploded by a spark, and converted into water vapor. The excess of air required in furnaces may be due to the presence of the great volumes of nitrogen and carbon dioxide, which dilutes the oxygen and makes it less active in causing combustion.

EXAMPLE.—How much air is required for the complete combustion of 1 lb. of coal containing 5% moisture, 20% volatile matter, 60% fixed carbon, 15% ash, assuming the volatile matter to be of the composition of marsh gas (methane), $CH_4$?

SOLUTION.—The molecular weight of marsh gas is $12+4=16$; hence, three-fourths of the weight of the volatile matter is carbon and one-fourth hydrogen. The carbon of the volatile matter is $\frac{3}{4}\times20=15\%$ of the fuel. The fixed carbon is given as 60%. The total carbon is $15+60=75\%$. The hydrogen of the volatile matter is $\frac{1}{4}\times20=5\%$ of the fuel.

As, from the table, 11.52 lb. of air is required to burn 1 lb. of carbon to $CO_2$, and 34.56 lb. of air is required to burn 1 lb. of hydrogen, the theoretical amount of air required to burn the fuel will be: For the carbon $.75\times11.52=8.640$ lb.; for the hydrogen $.05\times34.56=1.728$ lb.; making a total of 10.368 lb. If an excess of 50% of air is allowed, the amount will be $1.5\times10.368=15.552$ lb.

EXAMPLE.—How many cubic feet of dry air at 62° F. will be required in the preceding example?

SOLUTION.—The weight of 1 cu. ft. of air at a temperature of 62° F. and a barometric pressure of 29.92 is .0761 lb.; hence, 10.368 lb.$=10.368\div.0761$ $=136.24$ cu. ft. and 15.552 lb.$=15.552\div.0761=204.36$ cu. ft.

**Temperature of Ignition.**—Every combustible must be heated to a certain temperature, known as the temperature of ignition, or kindling point, before it will combine with oxygen, or burn. The accompanying table gives the temperatures of ignition of various fuels as determined by different authorities. It appears from this table that it requires a considerably higher temperature to ignite the gases distilled from coal than to ignite the coal itself, the temperature of ignition of the carbon being lower than that of the gases.

### TEMPERATURE OF IGNITION OF VARIOUS FUELS

| Fuel | Temperature of Ignition Degrees F |
|---|---|
| Marsh gas (methane), $CH_4$ | 1,202* |
| Carbon monoxide, $CO$ | 1,202 to 1,211 |
| Carbon monoxide, $CO$, in presence of a large quantity of carbon dioxide $CO_2$ | 1,292 |
| Ethylene (olefiant gas), $C_2H_4$ | 1,022 |
| Hydrogen | 1,031 to 1,130 |
| Anthracite | 925 |
| Semibituminous coal | 870 |
| Bituminous coal | 766 |
| Cannel coal | 668 |
| Soft charcoal, prepared at 500° F. | 650 |
| Sulphur | 470 |

*The temperature of ignition of marsh gas diluted with carbon dioxide and nitrogen in the proportions ordinarily found in a furnace is given by the French Coal Commission as 1,436° F.

**Temperature of Fire.**—Assuming that a pure fuel, such as carbon, is thoroughly burned in a furnace, all the heat generated will be transferred to the gaseous products of combustion, raising their temperature above that at which the fuel and the oxygen or air are supplied to the furnace. Suppose that 1 lb. of carbon is burned with 2⅔ lb. of oxygen, forming 3⅔ lb. of carbon dioxide, both the carbon and the oxygen being supplied at 0° F. The combustion of 1 lb. of carbon generates 14,600 B. T. U., which will all be contained in the 3⅔ lb. of carbon dioxide. The specific heat of carbon dioxide is .217 at constant pressure; that is, it requires .217 B. T. U. to raise the temperature of 1 lb. of carbon dioxide 1° F. To raise 3⅔ lb. of carbon dioxide 1° F. will require $3⅔ \times .217 = .7957$ B. T. U., and 14,600 B. T. U. will therefore raise its temperature $14,600 \div .7957 = 18,348.6°$ F. (approximately 18,350 F.) above the temperature at which the carbon and the oxygen were supplied. The temperatures thus calculated are known as theoretical temperatures, and are based on the assumptions of perfect combustion and no loss by radiation. The temperature of 18,350° is far beyond any temperature known, and it is probable that long before it could be reached, the phenomenon of dissociation would take place; that is, the carbon dioxide would be split into carbon and oxygen, and the elements would lose their affinity for each other.

The theoretical elevation of temperature of the fire may be calculated by the formula

29

## HEAT AND PRODUCTS OF COMBUSTION OF BURNING CARBON

### Carbon Burned Partly to CO₂ and Partly to CO With Excess of Air

| Degrees F. Elevation of Temperature of Fire | Pounds Chimney Gases (Air and Carbon) | Per Cent. Excess of Air | Per Cent. Carbon Burned to CO | Per Cent. Carbon Burned to CO₂ |
|---|---|---|---|---|
| 3,328 | 18.28 | 50 | 20 | 100 |
| 3,375 | 15.52 | 40 | 40 | 80 |
| 3,350 | 12.99 | 30 | 60 | 60 |
| 3,323 | 10.67 | 20 | 80 | 40 |
| 3,139 | 8.60 | 10 | 100 | 20 |
| 2,743 | 6.76 | | | |

### Carbon Burned to CO₂ With Excess of Air

| Degrees F. Elevation of Temperature of Fire | Pounds Chimney Gases (Air and Carbon) | Pounds Air per Pound of Carbon | Per Cent. Air Supply Above 11.52 Pounds |

$$\text{Elevation of temperature} = \frac{\text{B. T. U. generated by the combustion}}{\text{Weight of gaseous products} \times \text{their specific heats}}$$

It is evident from this formula that the rapidity of the combustion, or the time required to burn a given weight of fuel, has nothing to do with the temperature that may theoretically be attained. In practice, the temperature of a bed of coal in a furnace and that of the burning gases immediately above the coal are reduced, to some extent, by radiation; and as the quantity of heat radiated from a given mass of fuel is a function of the time during which it takes place, a considerable portion of the heat generated may be lost by radiation when the combustion is very slow. With ordinary rates of combustion, however, that is, of about 10 lb. of coal per square foot of grate surface per hour, and firebrick furnaces, the percentage of loss of heat by radiation is 1% or less, and the actual temperature that may be attained will be very nearly as high with that rate of combustion as with a rate of 20 or 40 lb.

The elevations of temperature given in the foregoing table were determined by means of the preceding formula, the specific heat of the chimney gases being taken as .24.

To burn 1 lb. of hydrogen, 8 lb. of oxygen is required, and there is also present $8 \times 3.32 = 26.56$ lb. of nitrogen, which is mixed with the oxygen in the air. The gaseous products are 9 lb. of water, in the shape of superheated steam (specific heat .48), and 26.56 lb. of nitrogen (specific heat .2438). The heat produced is 62,000 B. T. U. If the temperature of the atmosphere is 62° F., 150 B. T. U. is absorbed during the combustion in heating 1 lb. of water, $H_2O$, from 62° to 212° F. per lb., 965.8 B. T. U. in evaporating it at that temperature, and .48 $(T+t-212)$ in superheating it from 212° to the temperature $T+t$ of the fire, $T$ being the increase of temperature and $t$ the temperature of the atmosphere, which in this case is 62° F. All this heat may be recovered by condensing the steam and cooling the water of condensation to 62°. Therefore, the following equation is obtained:

$$62,000 = 9 \times [150 + 965.8 + .48 \times (T + 62 - 212)] + 26.56 \times .2438 T$$

which, being solved, gives $T = 4,873°$ F. $T + t = 4,935°$ F. Showing that hydrogen and carbon, when perfectly burned, give about the same maximum theoretical temperature.

By a process of reasoning similar to the preceding, the following formula is derived, to obtain the maximum theoretical temperature of the fire, when the fuel contains hydrogen and oxygen with a varying supply of air:

$$T = \frac{616C + 2,220H - 327O - 44W}{f + .02W + .18H},$$

in which  $T$ = elevation of temperature above that of atmosphere;
  $C$ = percentage of carbon in fuel;
  $H$ = percentage of hydrogen in fuel;
  $O$ = percentage of oxygen in fuel;
  $W$ = percentage of water in fuel;
  $f$ = pounds of dry gases of combustion ($H_2O$ excluded) per pound of fuel.

EXAMPLE.—What would be the temperature of the fire, the temperature of the atmosphere being 62° F., when burning a coal having the composition, excluding ash and sulphur, carbon 75%, hydrogen 5%, oxygen 10%, moisture 10%; the dry chimney gases amount to 20 lb. per lb. of this combustible, including the moisture?

SOLUTION.—Applying the formula,

$$T = \frac{616 \times 75 + 2,220 \times 5 - 327 \times 10 - 44 \times 10}{20 + .02 \times 10 + .18 \times 5} = 2,540° \text{ F.}$$
$$T + t = 2,540° + 62° = 2,602° \text{ F.}$$

EXAMPLE.—What is the maximum temperature attainable by burning moist wood of the composition carbon 38%, hydrogen 5%, oxygen 32%, nitrogen and ash 1%, moisture 24%; the dry gases are 15 lb. per lb. of wood, and the temperature of the atmosphere is 62° F.?

SOLUTION.—Applying the formula,

$$T = \frac{616 \times 38 + 2,220 \times 5 - 327 \times 32 - 44 \times 24}{15 + .02 \times 24 + .18 \times 5} = 1,403° \text{ F.}$$
$$T + t = 1,403° + 62° = 1,465° \text{ F.}$$

EXAMPLE.—What will be the temperature of a fire of Pocahontas coal analyzing carbon 84.22%, hydrogen 4.26%, oxygen 3.48%, nitrogen .84%, sulphur .59%, ash 5.85%, water .76%; the dry gases are 20 lb. per lb. of combustible, the heating value of the sulphur being neglected?

SOLUTION.—The combustible, carbon and hydrogen, is 88.48% of the coal, hence $f = 20 \times .8848 = 17.69$. Applying the formula,

$$T = \frac{616 \times 84.22 + 2,220 \times 4.26 - 327 \times 3.48 - 44 \times .76}{17.69 + .02 \times .76 + .18 \times 4.26} = 3,257° \text{ F.}$$

$$T + t = 3,257° + 62° = 3,319° \text{ F.}$$

When the combustion is perfect, and the furnace is entirely enclosed in walls of firebrick, highly heated, the temperatures calculated by the formula are nearly attained, the only loss being that due to external radiation. In ordinary practice, with the boiler immediately above the fire, the temperature is lowered by radiation, and also, when soft coal is used, by imperfect combustion.

**Estimation of Air Supply.**—The theoretical amounts of air required to burn the several combustible elements in a fuel were given in the table on page 447, but when burning coal in a furnace only a rough estimate of the quantity of air supplied may be obtained by direct measurement by an anemometer, or by counting the revolutions of a fan. The only available method of closely approximating the amount of air supplied, is by making a proximate analysis of the gases of combustion, taken from a point close to the furnace, but beyond the point of visible flame. If taken from the chimney, the gas may be of different composition on account of inward leaks of air through cracks in the brickwork.

The analysis of the gases gives the percentage of carbon dioxide, oxygen, and carbon monoxide, in this order, the quantity of these gases being determined by absorption; nitrogen is determined by difference; that is, the remainder after subtracting the sum of the other three gases from 100. Unburned hydrogen or hydrocarbon gases cannot be conveniently determined by ordinary analysis. If the combustion is complete, the percentage of nitrogen will always be found between 79 and 80. If it exceeds 80%, unburned hydrogen, or hydrocarbons are present, an error has been made in the analysis, or, possibly, the hydrogen of a gaseous fuel has been burned leaving the carbon unburned. Thus, in burning marsh gas (methane), $CH_4$, with an insufficient supply of air, the hydrogen only may be burned to water, $H_2O$, leaving the carbon unburned in the shape of soot, which is caught in a filter attached to the gas-collecting apparatus. The water, or water vapor, is condensed, and is not determined in the analysis, leaving the nitrogen that accompanied the oxygen alone to be determined. In this manner, the nitrogen in the gases may actually exceed 80%.

The following formula may be used for calculating the air supply:

$$\text{Pounds of dry air per pound of carbon} = \frac{3.032N}{CO_2 + CO}$$

in which $CO_2$, $CO$, and $N$ are percentages, by volume, of the dry gas.

EXAMPLE.—How many pounds of air are supplied per pound of carbon in burning a coal, if the gases analyze carbon dioxide 11.74%, carbon monoxide .10%, oxygen 7.71%, nitrogen 80.45%?

SOLUTION.—Substituting in the formula,

$$\frac{3.032 \times 80.45}{11.74 + .10} = 20.6 \text{ lb.}$$

**Production and Measurement of Draft.**—It is well known that any volume of gas is lighter when heated than the same volume of gas when cool. When hot gases pass into the chimney they have a temperature of from 400° to 600° F., while the air outside the chimney has a temperature of from 40° to 90° F. Roughly speaking, the air weighs twice as much, bulk for bulk, as the hot gases. Naturally, then, the pressure in the chimney is less than the pressure of the outside air. The production of draft and the satisfactory operation of a chimney depend on this pressure difference. The pressure of the draft depends on the temperature of the furnace gases and the height of the chimney. Chimney draft is affected by so many varying conditions that no absolutely reliable rules can be given for proportioning chimneys to give a certain desired draft pressure. The rules given for chimney proportions are based on successful practice rather than on pure theory.

The intensity of the draft may be measured by means of a water gauge such as is shown in the accompanying illustration. This is a glass tube open at both ends, bent to the shape of the letter **U**; the left leg communicates with the chimney. The difference in the two water levels $H$ and $Z$ in the legs represents the intensity of the draft, and is expressed in inches of water.

The draft produced by a chimney may vary from ¼ in. to 2 in. of water, depending on the temperature of the chimney gases and on the height of the chimney. Generally speaking, it is advantageous to use a high chimney and

as low a chimney temperature as possible. The draft pressure required depends on the kind of fuel used. Wood requires but little draft, say, $\frac{1}{4}$ in. of water or less; bituminous coal generally requires less draft than anthracite.

To burn anthracite slack, or culm, the draft pressure should be about $1\frac{1}{2}$ in. of water.

**Erection of Chimneys.**—The form of a chimney has a pronounced effect on its capacity. A round chimney has a greater capacity for a given area than a square one. If the flue is tapering, the area for calculation is measured at its smallest section. The flue through which the gases pass from the boilers to the chimney should have an area equal to, or a little larger than, the area of the chimney. Abrupt turns in the flue or contractions of its area should be carefully avoided. Where one chimney serves several boilers, the branch flue from each furnace to the main flue must be somewhat larger than its proportionate part of the area of the main flue.

Chimneys are usually built of brick, though concrete, iron, and steel chimneys are often used for those of moderate height. Brick chimneys are usually built with a flue having parallel sides and a taper on the outside of the chimney of from $\frac{1}{16}$ to $\frac{1}{4}$ in. per ft. of height. A round chimney gives greater draft area for the same amount of material in its structure and exposes less surface to the wind than a square chimney. Large brick stacks are usually made with an inner core and an outer shell, with a space between them. Such chimneys are usually constructed with a series of internal pilasters, or vertical ribs, to give rigidity. The top of the chimney should be protected by a coping of stone or a cast-iron plate to prevent the destruction of the brickwork by the weather.

Iron or steel stacks are made of plates varying from $\frac{1}{8}$ to $\frac{1}{2}$ in. thick. The larger stacks are made in sections, the plates being about $\frac{1}{4}$ in. thick at the top and increasing to $\frac{1}{2}$ in. at the bottom; they are lined with firebrick about 18 in. thick at the bottom and 4 in. at the top. Sometimes no lining is used on account of the likelihood of corrosion and the difficulty of inspection, and also because the inside of lined stacks cannot be painted.

On account of the great concentration of weight, the foundation for a chimney should be carefully designed. Good natural earth will support from 2,000 to 4,000 lb. per sq. ft. The footing beneath the chimney foundation should be made of large area, in order to reduce the pressure due to the weight of the chimney and its foundation to a safe limit.

**Height and Area of Chimneys.**—The relation between the height of the chimney and the pressure of the draft, in inches of water, is given by the formula

$$p = H\left(\frac{7.6}{T_a} - \frac{7.9}{T_c}\right),$$

in which

$$p = \text{draft pressure, in inches of water;}$$
$$H = \text{height of chimney, in feet;}$$
$$T_a \text{ and } T_c = \text{absolute temperatures of outside air and of chimney gases respectively.}$$

EXAMPLE.—What draft pressure will be produced by a chimney 120 ft. high, the temperature of the chimney gases being 600° F., and of the external air 60° F.?

SOLUTION.—Substituting in the formula,

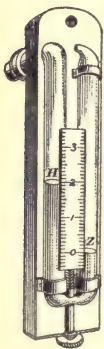
$$p = 120 \times \left(\frac{7.6}{460+60} - \frac{7.9}{460+600}\right) = .859 \text{ in.}$$

To find the height of chimney to give a specified draft pressure, the preceding formula may be transformed. Thus,

$$H = \frac{p}{\left(\dfrac{7.6}{T_a} - \dfrac{7.9}{T_c}\right)}$$

EXAMPLE.—Required, the height of the chimney to produce a draft of $1\frac{1}{8}$ in. of water, the temperature of the gases and of the external air being, respectively, 550° and 62° F.

SOLUTION.—Substituting in the formula,

$$H = \frac{1.125}{\dfrac{7.6}{522} - \dfrac{7.9}{1,010}} = 167 \text{ ft.}$$


In determining the height of a chimney in cities, it should be borne in mind that the chimney must almost always be carried to a height above the roofs of surrounding buildings, partly in order to prevent a nullification of the draft by opposing air-currents and partly to prevent the commission of a nuisance.

The height of the chimney being decided on, its cross-sectional area must be sufficient to carry off readily the products of combustion. The following formulas for finding the dimensions of chimneys are in common use:

Let
$\quad$ $H$ = height of chimney, in feet;
$\quad$ $H.P.$ = horsepower of boiler or boilers;
$\quad$ $A$ = actual area of chimney, in square feet;
$\quad$ $E$ = effective area of chimney, in square feet;
$\quad$ $S$ = side of square chimney, in inches;
$\quad$ $d$ = diameter of round chimney, in inches.

Then,
$$E = \frac{.3\ H.P.}{\sqrt{H}} = A - .6\sqrt{A} \quad (1)$$

$$H.P. = 3.33 E \sqrt{H} \quad (2)$$

$$S = 12\sqrt{E} + 4 \quad (3)$$

$$d = 13.54\sqrt{E} + 4 \quad (4)$$

The table on page 454 has been computed from these formulas.

EXAMPLE.—What should be the diameter of a chimney 100 ft. high that furnishes draft for a 600-H. P. boiler?

SOLUTION.—Substituting in formula 1, $E = \dfrac{.3 \times 600}{\sqrt{100}} = 18$. Now, using formula 4, $d = 13.54\sqrt{18} + 4 = 61.44$ in.

EXAMPLE.—For what horsepower of boilers will a chimney 64 in. sq. and 125 ft. high furnish draft?

SOLUTION.—By simply referring to the table, the horsepower is found to be 934.

**Maximum Combustion Rate.**—The maximum rates of combustion attainable under natural draft are given by the following formulas, which have been deduced from the experiments of Isherwood:

Let
$\quad$ $F$ = weight of coal per hour per square foot of grate area, in pounds;
$\quad$ $H$ = height of chimney or stack, in feet,

Then, for anthracite burned under the most favorable conditions,
$$F = 2\sqrt{H} - 1 \quad (1)$$
and under ordinary conditions,
$$F = 1.5\sqrt{H} - 1 \quad (2)$$
For best semianthracite and bituminous coals,
$$F = 2.25\sqrt{H} \quad (3)$$
and for less valuable soft coals,
$$F = 3\sqrt{H} \quad (4)$$

The maximum rate of combustion is thus fixed by the height of the chimney; the minimum rate may be anything less.

EXAMPLE.—Under ordinary conditions, what is the maximum rate of combustion of anthracite if the chimney is 120 ft. high?

SOLUTION.—By formula 2,
$$F = 1.5 \times \sqrt{120} - 1 = 15\tfrac{1}{2} \text{ lb. per sq. ft. per hr.}$$

**Forced Draft.**—The use of forced draft as a substitute for, or as an aid to, natural chimney draft is becoming quite common in large boiler plants. Its advantages are that it enables a boiler to be driven to its maximum capacity to meet emergencies without reference to the state of the weather or to the character of the coal; that the draft is independent of the temperature of the chimney gases, and that, therefore, lower flue temperatures may be used than with natural draft; and in many cases that it enables a poorer quality of coal to be used than is required with natural draft. Forced draft may be obtained: (1) by a steam jet in the chimney, as in locomotives and steam fire-engines; (2) by a steam-jet blower under the grate bars; (3) by a fan blower delivering air under the grate bars, the ash-pit doors being closed; (4) by a fan blower delivering air into a closed fireroom, as in the *closed stoke-hold system* used in some ocean-going vessels; and (5) by a fan placed in the flue or chimney drawing the gases of combustion from the boilers, commonly called the *induced-draft system.* Which one of these several systems should be adopted in any special

*Height of Chimney, in Feet* — *Commercial Horsepower*

case will usually depend on local conditions. The steam jet has the advantage of lightness and compactness of apparatus, and is therefore most suitable for locomotives and steam fire-engines, but it also is the most wasteful of steam, and therefore should not be used when one of the fan-blower systems is available, except for occasional or temporary use, or when very cheap fuel, such as anthracite culm at the mines, is used.

---

# STEAM ENGINES

---

## PRINCIPLES AND REQUIREMENTS

A good steam engine should be as direct acting as possible; that is, the connecting parts between the piston and the crank-shaft should be few in number, as each part wastes some power. The moving parts of an engine should be strong, to resist strains, and light, so as to offer no undue resistance to motion; parts moving upon each other should be well, truly, and smoothly finished, to reduce resistances to a minimum; the steam should get into the cylinder easily at the proper time, and the exhaust should leave the cylinder as exactly and as easily. The steam pipes supplying steam should have an area one-tenth the combined areas of the cylinders they supply, and exhaust pipes should be somewhat larger. The cylinder and the steam pipes and the boiler should be well protected. The engine should be capable of being started and stopped and reversed easily and quickly.

**Clearance.**—The term clearance is used in two senses in connection with the steam engine. It may be the distance between the piston and the cylinder head when the piston is at the end of its stroke, or it may represent the volume between the piston and the valve when the engine is on dead center. To avoid confusion, the former is called *piston clearance*, and the latter is termed simply *clearance.* Piston clearance is always a measurement, expressed in parts of an inch. Clearance, however, is a volume.

The clearance of an engine may be found by putting the engine on a dead center and pouring in water until the space between the piston and the cylinder head, and the steam port leading into it, is filled. The volume of the water poured in is the clearance. The clearance may be expressed in cubic feet or cubic inches, but it is more convenient to express it as a percentage of the volume swept through by the piston. For example, suppose that the clearance volume of a $12'' \times 18''$ engine is found to be 128 cu. in. The volume swept through by the piston per stroke is $12^2 \times .7854 \times 18 = 2,035.8$ cu. in. Then, the clearance is $128 \div 2,035.8 = .063 = 6.3\%$. The clearance may be as low as $\frac{1}{2}\%$ in Corliss engines, and as high as $14\%$ in high-speed engines.

Theoretically, there should be no clearance, because the steam that fills the clearance space does no work except during expansion; it is exhausted from the cylinder during the return stroke, and represents so much dead loss. This is remedied, to some extent, by compression. If the compression were carried up to the boiler pressure, there would be very little, if any, loss, as the steam would then fill the entire clearance space at boiler pressure, and the amount of fresh steam needed would be the volume displaced by the piston up to the point of cut-off, the same as if there were no clearance. In practice, however, the compression is made only sufficiently great to cushion the reciprocating parts and bring them to rest quietly.

It is not practicable to build an engine without any clearance, on account of the formation of water in the cylinder due to the condensation of steam, particularly when starting the engine. Automatic cut-off high-speed engines of the best design, with shaft governors, usually compress to about half the boiler pressure, and have a clearance of from 7 to 14%. Corliss engines require but very little compression, owing to their low rotative speeds; they also have very little clearance, as the ports are short and direct.

**Cut-Off.**—The *apparent cut-off* is the ratio between the portion of the stroke completed by the piston at the point of cut-off, and the total length of the stroke. For example, if the length of stroke is 48 in., and the steam is cut off from the cylinder just as the piston has completed 15 in. of the stroke, the apparent cut-off is $\frac{15}{48} = \frac{5}{16}$.

The *real cut-off* is the ratio between the volume of steam in the cylinder at the point of cut-off and the volume at the end of the stroke, both volumes including the clearance of the end of the cylinder in question. If the volume of steam in the cylinder, including the clearance, at the point of cut-off is 4 cu. ft., and the volume, including the clearance, at the end of the stroke is 6 cu. ft., the real cut-off is $\frac{4}{6} = \frac{2}{3}$.

**Ratio of Expansion.**— The ratio of expansion, also called the *real number of expansions*, is the ratio between the volume of steam, including the steam in the clearance space, at the end of the stroke, and the volume, including the clearance, at the point of cut-off. It is the reciprocal of the real cut-off. For example, if the volume at the end of the stroke is 8 cu. ft., and the cut-off is 5 cu. ft., the ratio of expansion is $8 \div 5 = 1.6$; in other words, the steam would be said to have one and six-tenths expansions. The corresponding real cut-off will be $\frac{5}{8}$.

Let
$e$ = real number of expansions;
$i$ = clearance, expressed as a per cent. of stroke;
$k$ = real cut-off;
$k_1$ = apparent cut-off;
$r$ = apparent number of expansions = $\dfrac{1}{k_1}$.

Then,
$$e = \frac{1}{k} \text{ and } k = \frac{1}{e} \quad (1)$$

$$k = \frac{k_1 + i}{1 + i} \quad (2)$$

**EXAMPLE.**—The length of stroke is 36 in.; the steam is cut off when the piston has completed 16 in. of the stroke; the clearance is 4%. Find the apparent cut-off, the real cut-off, and the real number of expansions.

SOLUTION.—Apparent cut-off = $\frac{16}{36} = \frac{4}{9} = .444$.

Real cut-off = $k = \dfrac{k_1 + i}{1 + i} = \dfrac{.444 + .04}{1 + .04} = \dfrac{.484}{1.04} = .465$.

Real number of expansions = $e = \dfrac{1}{k} = \dfrac{1}{.465} = 2.15$.

**Mean Effective Pressure.**—In order to find the horsepower of an engine, it is necessary to know the *mean effective pressure* (abbreviated M. E. P.),

which is defined as the average pressure urging the piston forwards during its entire stroke in one direction, less the pressure that resists its progress. If an indicator is not available, so that diagrams may be taken in order to determine the mean effective pressure of an engine, the value of this pressure may be estimated by the formula

$$P = .9[C(p+14.7)-17],$$

in which　　　$P$ = M. E. P., in pounds per square inch;
　　　　　　　$C$ = constant corresponding to cut-off, taken from following table;
　　　　　　　$p$ = boiler pressure, in pounds per square inch, gauge.

The foregoing formula applies only to a simple noncondensing engine. If the engine is a simple condensing engine, the formula should be altered by substituting for 17 the pressure existing in the condenser, in pounds per square inch.

## CONSTANTS USED IN CALCULATING MEAN EFFECTIVE PRESSURE

| Cut-off | Constant | Cut-off | Constant | Cut-off | Constant |
|---------|----------|---------|----------|---------|----------|
| $\frac{1}{6}$ | .545 | $\frac{3}{8}$ | .773 | $\frac{2}{3}$ | .943 |
| $\frac{1}{5}$ | .590 | .4 | .794 | .7 | .954 |
| $\frac{1}{4}$ | .650 | $\frac{1}{2}$ | .864 | $\frac{3}{4}$ | .970 |
| .3 | .705 | .6 | .916 | .8 | .981 |
| $\frac{1}{3}$ | .737 | $\frac{5}{8}$ | .927 | $\frac{7}{8}$ | .993 |

In this table, the fraction indicating the point of cut-off is obtained by dividing the distance that the piston has traveled when the steam is cut off by the whole length of the stroke; that is, it is the apparent cut-off. It is to be observed that this rule cannot be applied to a compound engine or to any other engine in which the steam is expanded in successive stages in several cylinders.

EXAMPLE.—Find the approximate mean effective pressure of a non-condensing engine cutting off at one-half stroke, if the boiler pressure is 80 lb., gauge.

SOLUTION.—According to the table, the constant corresponding to cut-off at one-half stroke is $C = .864$. Then, applying the formula, $P = .9 \times [.864 \times (80+14.7) - 17] = 58.34$ lb. per sq. in.

**Horsepower.**—The indicator furnishes the most ready method of measuring the pressures on the piston of a steam engine and, in consequence, of determining the amount of work done in the cylinder and the corresponding horsepower. The power measured by the use of the indicator is called the *indicated horsepower*. It is the total power developed by the action of the net pressures of the steam on the two sides of the moving piston. The indicated horsepower is generally represented by the initials I. H. P.

The part of the indicated horsepower that is absorbed in overcoming the frictional resistances of the moving parts of the engine is termed the *friction horsepower*. If the engine is running light, or with no load, all the power developed in the cylinder is absorbed in keeping the engine in motion, and the friction horsepower is equal to the indicated horsepower. This principle furnishes a simple approximate method of finding the friction horsepower of a given engine; as, however, the friction between the surfaces increases with the pressure, the power absorbed in overcoming the engine will be greater as the load on the engine is increased.

The difference between the indicated horsepower and the friction horsepower is the *net horsepower*. This is the power that the engine delivers through the flywheel or shaft to the belt or the machine driven by it, and is sometimes called the *delivered horsepower*. As the power that an engine is capable of delivering when working under certain conditions is often measured by a device known as a Prony brake, the net horsepower is frequently called the *brake horsepower*, abbreviated B. H. P.

**Finding the Indicated Horsepower.**—Knowing the dimensions and speed of the engine and the mean effective pressure on the piston, all the data for finding the rate of work done in the engine cylinder expressed in horsepower are at hand.

Let        $H$ = indicated horsepower of engine;

$P$ = mean effective pressure of the steam, in pounds per square inch;

$A$ = area of piston, in square inches;

$L$ = length of stroke, in feet;

$N$ = number of working strokes per minute.

Then,
$$H = \frac{P\ L\ A\ N}{33,000}$$

In a double-acting engine, or one in which the steam acts alternately on both sides of the piston, the number of working strokes per minute is twice the number of revolutions per minute. For example, if a double-acting engine runs at a speed of 210 R. P. M. there are 420 working strokes per minute. A few types of engines, however, are single-acting; that is, the steam acts on only one side of the piston. Such are the Westinghouse, the Willans, and others. In this case, only one stroke per revolution does work, and, consequently, the number of strokes per minute to be used in the foregoing formula is the same as the number of revolutions per minute. Unless it is specifically stated that an engine is single-acting, it is always understood, when the dimensions of a steam engine are given, that a double-acting engine is meant.

EXAMPLE.—The diameter of the piston of an engine is 10 in. and the length of stroke 15 in. It makes 250 R. P. M., with a mean effective pressure of 40 lb. per sq. in. What is the horsepower?

SOLUTION.—As it is not stated whether the engine is single or double acting, assume that it is double acting; then, the number of strokes is $250 \times 2 = 500$ per min. Hence,

I. H. P. = $\dfrac{P\ L\ A\ N}{33,000} = \dfrac{40 \times 1\frac{1}{4} \times (10^2 \times .7854) \times 500}{33,000} = 59.5$ H. P.

The indicated horsepower of a compound or triple-expansion engine may be calculated from the indicator diagrams in exactly the same manner as with any simple engine, considering each cylinder as a simple engine and adding the horsepowers of the several cylinders together. In taking the indicator cards from a compound engine, the precaution of taking the cards simultaneously from all cylinders must be observed, especially when the engine runs under a variable load, because, otherwise, an entirely wrong distribution of power may be shown, and there may also be a great variation between the indicated horsepower really existing and that calculated from diagrams taken at different times.

The indicated horsepower of compound engines is sometimes found by referring the mean effective pressure of the high-pressure cylinder to the low-pressure cylinder and calculating the horsepower of the engine on the assumption that all the work is done in the low-pressure cylinder. To do this, the mean effective pressures of the two cylinders are found from indicator diagrams; the mean effective pressure of the high-pressure cylinder is then divided by the ratio of the volume of the low-pressure cylinder to that of the high-pressure cylinder; and the quotient is added to the mean effective pressure of the low-pressure cylinder, the sum being the *referred mean effective pressure*. This sum is then taken as the mean effective pressure of the engine, and the area of the low-pressure piston as the piston area; with these data, the length of stroke and the number of strokes, the horsepower is computed as for any simple engine. In the case of a triple-expansion engine, the mean effective pressures of the high-pressure and intermediate cylinders are referred to the low-pressure cylinder and added to its mean effective pressure. Thus, suppose that in a 12″, 20″, and 34″×30″ engine the mean effective pressures are 82.3 lb., 27.8 lb., and 10.6 lb., respectively. Then, the referred mean effective pressure is $\dfrac{83.2}{8.03} + \dfrac{27.8}{2.78} + \dfrac{10.6}{1} = 10.4 + 10 + 10.6 = 31$ lb., and this value must be substituted for $P$ in finding the horsepower of the engine. While this method shortens the labor of computing the horsepower, it obviously does not show the distribution of work between the cylinders.

**Stating Sizes of Engines.**—The size of a simple engine, that is, an engine having but one cylinder, is commonly stated by giving the diameter of the cylinder, followed by the length of the stroke, both in inches. Thus, a simple engine having a cylinder 12 in. in diameter and a stroke of 24 in. would be referred to as a 12″×24″ engine, the multiplication sign in this case serving merely to separate the two numbers. The sizes of compound and multiple-expansion engines are designated in a similar fashion. Thus, a compound engine with a high-pressure cylinder 11 in. in diameter, a low-pressure cylinder

20 in. in diameter, and a stroke of 15 in. would be referred to as an $11''$ and $20'' \times 15''$ compound engine. In the same way, a $14''$, $22''$, and $34'' \times 18''$ triple-expansion engine would be one in which the diameters of the cylinders are 14 in., 22 in., and 34 in., and the stroke is 18 in.

**Mechanical Efficiency.**—The mechanical efficiency of an engine is the ratio of the net horsepower to the indicated horsepower; or it is the percentage of the mechanical energy developed in the cylinder that is utilized in doing useful work. To find the efficiency of an engine, when the indicated and net horsepowers are known, divide the net horsepower by the indicated horsepower.

**Piston Speed.**—The total distance traveled by the piston in 1 min. is called the *piston speed*. As it is customary to take the stroke in inches, to find the piston speed, multiply the stroke in inches by the number of strokes and divide by 12; or, letting $S$ represent the piston speed, $S = \dfrac{lN}{12}$, where $l$ is the stroke in inches. But $N = 2R$, where $R$ represents the number of revolutions per minute. Hence,

$$S = \frac{lN}{12} = \frac{l \times 2R}{12} = \frac{lR}{6}$$

**EXAMPLE.**—An engine with a 52-in. stroke runs at a speed of 66 R. P. M. What is the piston speed?

**SOLUTION.**—By the formula, $S = \dfrac{52 \times 66}{6} = 572$ ft. per min.

The piston speeds used in modern practice are about as follows:

| Type of Engine | Piston Speed Ft. per Min. |
|---|---|
| Small stationary engines | 300 to 600 |
| Large stationary engines | 600 to 1,000 |
| Corliss engines | 400 to 750 |
| Marine engines | 200 to 1,200 |

**Allowance for Area of Piston Rod.**—It is generally considered sufficiently accurate to take the total area of one side of the piston as the area to be used in calculating the horsepower of an engine. The effective area of one side of the piston is, however, reduced by the sectional area of the piston rod, and if it is important that the power be calculated with the greatest practical degree of accuracy, an allowance for the area of the piston rod must be made. This is done by taking as the piston area one-half the sum of the areas exposed to steam pressure on the two sides of the piston. Thus, if a piston is 30 in. in diameter with a 6-in. piston rod, the average area is

$$\frac{30^2 \times .7854 + (30^2 \times .7854 - 6^2 \times .7854)}{2} = 692.72 \text{ sq. in.}$$

If the piston rod is continued past the piston so as to pass through the head-end cylinder head; that is, if the piston has a *tailrod*, allowance must be made for the tailrod. Thus, with a piston 30 in. in diameter, a piston rod 6 in. in diameter, and a tailrod 5 in. in diameter, the average area is

$$\frac{(30^2 \times .7854 - 5^2 \times .7854) + (30^2 \times .7854 - 6^2 \times .7854)}{2} = 682.9 \text{ sq. in.}$$

**Cylinder Ratios.**—The cylinders of compound and multiple-expansion engines increase in diameter from the high-pressure to the low-pressure end, and it is customary to refer to their relative sizes by means of cylinder ratios. As all the cylinders have the same length of stroke, the volumes of the several cylinders are in proportion to the areas of the cylinders, and therefore in proportion to the squares of the diameters. The area of the high-pressure cylinder is taken as unity, and the other areas are referred to it, and the ratios of these areas, or the ratios of the squares of the diameters, are called the *cylinder ratios*. For example, a triple-expansion engine having cylinders 12 in., 20 in., and 34 in. in diameter will have the cylinder ratios of $12^2 : 20^2 : 34^2$, or $144 : 400 : 1,156$, which reduces to $1 : 2.78 : 8.03$; that is, the intermediate cylinder is 2.78 times as large as the high-pressure cylinder and the low-pressure cylinder is 8.03 times as large as the high-pressure cylinder. If there are two cylinders to one stage of expansion, as, for example, two low-pressure cylinders, the sum of their areas must be used in finding the cylinder ratios. Thus, if there had been two 24-in. low-pressure cylinders instead of one 34-in. cylinder, in the foregoing case, the cylinder ratios would have been $12^2 : 20^2 : 2 \times 24^2$, or $144 : 400 : 1,152$, which reduces to $1 : 2.78 : 8$.

# CONDENSERS

There are two types of condensers in general use, namely, the *surface condenser* and the *jet condenser*. In the former, the exhaust steam comes in contact with a large area of metallic surface that is kept cool by contact with cold water. In the latter, the exhaust steam, on entering the condenser, comes in contact with a jet of cold water. In either case, the entering steam is condensed to water, and in consequence a partial vacuum is formed. If enough cold water were used, the steam on entering would instantly condense and a practically perfect vacuum would be obtained were it not for the fact that the feedwater of the boiler always contains a small quantity of air, which passes with the exhaust steam into the condenser and therefore partly destroys the vacuum. To get rid of this air, the condenser is fitted with an air pump, which pumps out both the air and the water formed by condensation.

**Surface Condensers.**—In the surface condenser, the exhaust steam and the injection water are kept separate throughout their course through the condenser; and the condensed steam leaves the condenser as fresh water, free from the impurities contained in the injection water. The water of condensation from a surface condenser is therefore fit to be used as boiler feed, except that it contains oil used for cylinder lubrication, which can be eliminated by means of an oil separator. It is for this reason that the surface condenser, in spite of its greater complication, cost, size, and weight, as compared with the jet condenser, is used instead of the latter where the supply of injection water is unfit for use as boiler feed. Thus, the surface condenser is used altogether in marine work, except for vessels navigating clean, fresh water like that of the Great Lakes, in order to avoid the use of sea-water in the boilers.

In the surface condenser the steam may be outside and the water inside the tubes, or the reverse. If the water is inside the tubes, it should enter at the bottom of the condenser and be discharged at the top. This brings the coldest water into contact with the partly condensed steam, and the warmest water into contact with the hot entering steam. When the water is outside the tubes, it is necessary to fit baffle plates on the water side to force the water into a definite and regular circulation, and to prevent it from going directly from inlet to outlet and also to prevent the water from arranging itself in layers according to temperature, with the coldest water on the bottom and the hottest water on top. The outlet should be well above the top row of tubes. A solid body of water above the top row of tubes is thus assured, and the accumulation of a stagnant body of hot water in the top of the condenser is prevented by its being continually drawn off by the circulating pump and replaced by cooler water from beneath.

Air tends to accumulate in the top of the water side of a surface condenser. This is particularly inconvenient where the water is inside the tubes, as the air fills the top rows of tubes and excludes the water, destroying their value as cooling surfaces. To prevent this, an air valve must be provided, as high up on the water side as possible, by which the air can be drawn off when it becomes troublesome. Drain valves and pipes should be provided at the bottom.

As the condensed steam from the surface condenser is generally pumped back into the boiler as feedwater, it is desirable to have it as hot as possible; but it must be remembered that it is impossible to get the feedwater from the condenser at a higher temperature than that of saturated steam at the absolute pressure existing in the condenser.

It will be considerably cooler than this if, after being condensed, it is allowed to lie in the bottom of the condenser and give up its heat to the circulating water. The heat thus given up is a total loss, and should be avoided by connecting the air-pump suction to the lowest point of the condenser and by shaping the bottom of the condenser so that the water will drain rapidly into the air-pump suction.

**Cooling Water for Surface Condenser.**—The amount of cooling water required in the case of a surface condenser may be found by the formula

$$Q = \frac{H - (t - 32)}{t_2 - t_1},$$

in which $Q$ = number of pounds of cooling water required to condense 1 lb. of steam;

$H$ = total heat above 32° of 1 lb. of steam at pressure at release;

$t$ = temperature of condensed steam on leaving condenser;

$t_1$ = temperature of cooling water on entering condenser;

$t_2$ = temperature of cooling water on leaving condenser.

**EXAMPLE.**—Steam exhausts into a surface condenser from an engine cylinder at a pressure of 6 lb., absolute; the temperature of the condensing water on entering is 55° F., and on leaving it is 100° F.; the temperature of the condensed steam on leaving the condenser is 125° F. How many pounds of cooling water are required per pound of steam?

**SOLUTION.**—The total heat above 32° of 1 lb. of steam at 6 lb., absolute, from the Steam Table, is 1,133.8 B. T. U. Then, substituting the values of $H$, $t$, $t_1$, and $t_2$ in the formula,

$$Q = \frac{1,133.8 - (125 - 32)}{100 - 55} = \frac{1,040.8}{45} = 23.13 \text{ lb.}$$

**Injection Water for Jet Condenser.**—The quantity of injection water required for a jet condenser may be found by the formula

$$Q = \frac{H - (t - 32)}{t - t_1},$$

in which $Q$ = number of pounds of injection water required to condense 1 lb. of steam;

$H$ = total heat above 32° of 1 lb. of steam at pressure at release;

$t$ = temperature of mixture of injection water and condensed steam on leaving the condenser;

$t_1$ = temperature of injection water on entering the condenser.

**EXAMPLE.**—Steam is exhausted into a jet condenser from an engine cylinder at a pressure of 10 lb., absolute; the temperature of the injection water on entering is 60° F., and on leaving 140° F. How much injection water is required per pound of steam?

**SOLUTION.**—The total heat above 32° of 1 lb. of steam at 10 lb. absolute, from the Steam Table, is 1,140.9 B. T. U. Then, substituting the values of $H$, $t$, and $t_1$ in the formula.

$$Q = \frac{1,140.9 - (140 - 32)}{140 - 60} = \frac{1,032.9}{80} = 12.91 \text{ lb.}$$

---

# ENGINE MANAGEMENT

## STARTING AND STOPPING

**Warming Up.**—About 15 or 20 min. before starting the engine, the stop-valves should be raised just off their seats and a little steam should be allowed to flow into the steam pipe. The drain cock on the steam pipe just above the throttle should be opened. When the steam pipe is thoroughly warmed and steam blows through the drain pipe, the drain cock should be closed and the throttle opened just enough to let a little steam flow into the valve chest and cylinder; or if a by-pass around the throttle is fitted, it may be used. The cylinder relief valves, or drain cocks, and also the drain cocks on the valve chest and the exhaust pipe should be opened, if the engine is non-condensing. If the cylinders are jacketed, steam should be turned into the jackets and the jacket drain cocks should be opened. While the engine is warming up, the oil cups and the sight-feed lubricator may be filled. A little oil may be put into all the small joints and journals that are not fitted with oil cups. The guides should be wiped off with oily waste and oiled. By this time the engine is getting warm. If the cylinder is fitted with by-pass valves, they should be used to admit steam to both ends of the cylinder. In general, all cylinders, especially if they are large and intricate castings, should be warmed up slowly, as sudden and violent heating of a cylinder of this character is very liable to crack the casting by unequal expansion.

An excellent and economical plan for warming up the steam pipe and the engine is to open the stop-valves and throttle valve at the time or soon after the fires are lighted in the boilers, permitting the heated air from the boilers to circulate through the engine, thus warming it up gradually and avoiding the accumulation of a large quantity of water of condensation in the steam pipe and cylinder. When pressure shows on the boiler gauge or steam at the drain pipes of the engine, the stop-valves and throttle may be closed temporarily, but not hard down on their seats. When this method of warming up the engine is adopted, the safety valves should not be opened while steam is being raised.

Stop-valves and throttle valves should never be opened quickly or suddenly and thus permit a large volume of steam to flow into a cold steam pipe or cylinder. If this is done, the first steam that enters will be condensed and a partial vacuum will be formed. This will be closely followed by another rush of steam

with similar results, and so on until a mass of water will collect, which will rush through the steam pipe and strike the first obstruction, generally the bend in the steam pipe near the cylinder, with great force and in all probability will carry it away and cause a disaster. This is called *water hammer* and has caused many serious accidents. Before turning steam into any pipe line or into a cylinder, all drain valves should be opened.

Another precaution that should be taken is the easing of the throttle valve on its seat before steam is let into the main steam pipe; otherwise, the unequal expansion of the valve casing may cause the valve to stick fast and thereby give much trouble. Even if a by-pass pipe is fitted around the throttle, it is better not to depend on it. As water is non-compressible, it is an easy matter to blow off a cylinder head or break a piston if the engine is started when there is a quantity of water in the cylinder.

**Oil and Grease Cups.**—The last thing for the engineer to do before taking his place at the throttle preparatory to starting the engine, provided he has no oiler, is to start the oil and grease cups feeding. It is well to feed the oil liberally at first, but not to the extent of wasting it; finer adjustment of the oiling gear can be made after the engine has been running a short time and the journals are well lubricated.

**Starting and Stopping Non-Condensing Slide-Valve Engine.**—A non-condensing slide-valve engine is started by simply opening the throttle; this should be done quickly in order to jump the crank over the first dead center, after which the momentum of the flywheel will carry it over the other centers. The engine should be run slowly at first, gradually increasing the revolutions to the normal speed. When the engine has reached full speed, the drain pipes should be examined; if dry steam is blowing through them, the drain cocks should be closed. If water is being delivered, the drain cocks should remain open until steam blows through and should then be closed.

To stop a non-condensing slide-valve engine, it is only necessary to shut off the supply of steam by closing the throttle, but care should be taken not to let the engine stop on the dead center. After the engine is stopped, the oil feed should be shut off and the main stop-valve closed. The valve should be seated, but without being jammed hard down on its seat. The drain cocks on the steam pipe and engine may or may not be opened, according to circumstances. It will do no harm to allow the steam to condense inside the engine, as the engine will then cool down more gradually, which lessens the danger of cracking the cylinder casting by unequal contraction. All the water of condensation should be drained from the engine before steam is again admitted to it.

**Starting and Stopping Condensing Slide-Valve Engine.**—In the case of condensing slide-valve engines, before the main engine is started, the air pump and circulating pump should be put into operation and a vacuum formed in the condenser; this will materially assist the main engine in starting promptly. Prior to starting the air and circulating pumps, the injection valve should be opened to admit the condensing water into the circulating pump; the delivery valve should also be opened at this time. If an ordinary jet condenser is used, no circulating pump is required, the water being forced into the condenser by the pressure of the atmosphere. If the air pump is operated by the main engine a vacuum will not be formed in the condenser until after the engine is started and at least one upward stroke of the air pump is made. In this case the injection valve must be opened at the same moment the engine is started; otherwise, the condenser will get hot and a mixture of air and steam accumulate in it and prevent the injection water from entering. When this occurs it is necessary to pump cold water into the condenser by one of the auxiliary pumps through a pipe usually fitted for that purpose; if such a pipe has not been provided, it may be found necessary to cool the condenser by playing cold water on it through a hose.

The operation of stopping a slide-valve surface-condensing engine is precisely similar to that of stopping a non-condensing engine of the same type, with the addition that after the main engine is stopped the air and circulating pumps are also stopped, and in the same way, that is, by closing the throttle, after which the injection valve and the discharge valve should be closed and the drain cocks opened. With a jet condenser, the operation of stopping the engine is the same as the above, with the exception that the injection valve should be closed at the same moment that the engine is stopped.

**Starting and Stopping Simple Corliss Engine.**—In the Corliss engine the eccentric rod is so constructed and arranged that it may be hooked on or unhooked from the eccentric pin on the wrist-plate at the will of the engineer.

After all the preliminary operations have been attended to, the starting bar is shipped into its socket in the wristplate and the throttle is opened. The starting bar is then vibrated back and forth by hand, by which the steam and exhaust valves are operated through the wristplate and valve rods; as soon as the cylinder takes steam, the engine will start. After working the starting bar until the engine has made several revolutions and the flywheel has acquired sufficient momentum to carry the crank over the dead centers, the hook of the eccentric rod should be allowed to drop upon the pin on the wristplate. As soon as the hook engages with the pin, the starting bar is unshipped and placed in its socket in the floor. The way to determine in which direction the starting bar should be first moved to start the engine ahead is to note the position of the crank, from which the direction in which the piston is to move may be learned. This will indicate which steam valve to open first; it will then be an easy matter to determine in which direction the starting bar should be moved. If the engine is of the condensing type, the same course of procedure in starting the air and circulating pumps should be followed as with the simple condensing slide-valve engine.

A Corliss engine is stopped by closing the throttle and unhooking the eccentric rod from the pin on the wristplate; this is done by means of the unhooking gear provided for the purpose. As soon as the eccentric rod is unhooked from the pin, the starting bar is shipped into its socket in the wristplate and the engine is worked by hand to any point in the revolution of the crank at which it is desired to stop the engine. The procedure is then the same as for the simple slide-valve engine. After stopping a Corliss condensing engine the same course should be followed as with a slide-valve condensing engine in regard to draining cylinders, closing stop-valves, etc.

**Starting and Stopping Compound Slide-Valve Engine.**—Before starting a compound engine, the high-pressure cylinder is warmed up in the same manner as a simple engine. To get the steam into the low-pressure cylinder is, however, an operation that will depend on circumstances. If the cylinders are provided with pass-over valves, it will be necessary only to open them to admit steam into the receiver and thence into the low-pressure cylinder. If the cylinders are not fitted with pass-over valves the steam can usually be worked into the receiver and low-pressure cylinder by operating the high-pressure valves by hand. Sometimes compound engines are fitted with starting valves, which greatly facilitate the operations of warming up and starting. Usually a compound engine will start upon opening the throttle.

If the high-pressure crank of a cross-compound engine is on its center and the low-pressure engine will not pull it off, it must be jacked off. If the pressure of steam in the receiver is too high, causing too much back pressure in the high pressure cylinder, the excess of pressure must be blown off through the receiver safety valve; if the pressure in the receiver is too low to start the low-pressure piston, more steam must be admitted into the receiver. If the engine is stuck fast from gummy oil or rusty cylinders, all wearing surfaces must be well oiled and the engine jacked over at least one entire revolution. If the cut-offs are run up, they should be run down, full open. If there is water in the cylinders, it should be blown out through the cylinder relief or drain valves, and if there is any obstruction to the engine turning, it should be removed.

If the crank of a tandem compound engine is on the center, it must be pulled or jacked off. If the high-pressure crank of a cross-compound engine is on the center, it may or may not be possible to start the engine by the aid of the low-pressure cylinder, depending on the valve gear and the crank arrangement. When the cranks are 180° apart, which is a very rare arrangement, the crank must be pulled or jacked off the center. When the cranks are 90° apart and a pass-over valve is fitted, live steam may be admitted into the receiver and thence into the low-pressure cylinder, in order to start the engine. When no pass-over is fitted, but the engine has a link motion, sufficient steam to pull the high-pressure crank off the center can generally be worked into the low-pressure cylinder by working the links back and forth. When no pass-over is fitted, but the high-pressure engine can have its valve or valves worked by hand, steam can be got into the low-pressure engine by working the high-pressure valve or valves back and forth by hand. If no way exists of getting steam into the low-pressure cylinder while the high-pressure crank is on a dead center, it must be pulled or jacked off.

If the air and circulating pumps are attached to and operated by the main engine, a vacuum cannot be generated in the condenser until after the main engine has been started. Consequently, in this case, there is no vacuum to help start the engine; therefore, if it is tardy or refuses to start, it will be

necessary to resort to the jacking gear and jack the engine into a position from which it will start. A vacuum having been generated in the condenser beforehand, the pressure in the receiver acting on the low-pressure piston causes the engine to start promptly, even though the high-pressure crank may be on its center.

Compound slide-valve engines, whether condensing or non-condensing, are stopped by closing the throttle, and, if a reversing engine, throwing the valve gear into mid-position. If the stop is a permanent one, the usual practice of draining the engine, steam chests, and receiver, closing stop-valves, stopping the oil feed, etc. should be followed. If the engine is intended to run in both directions in answer to signals, as in the cases of hoisting, rolling-mill, and marine engines, the operator, after stopping the engine on signal, should immediately open the throttle very slightly, in order to keep the engine warm, and stand by for the next signal. If the engine is fitted with an independent or adjustable cut-off gear, it should be thrown off; that is, set for the greatest cut-off, for the reason that the engine may have stopped in a position in which the cut-off valves in their early cut-off positions would permit little or no steam to enter the cylinders, in which case the engine will not start promptly, and perhaps not at all. While waiting for the signal, the cylinder drain valves should be opened and any water that may be in the cylinders should be blown out. When dry steam blows through the drains, the cylinders are clear of water.

When the signal to start the engine is received, it is only necessary to throw the valve gear into the go-ahead or backing position, as the signal requires, and to operate the throttle according to the necessities of the case, for which no rule can be laid down beforehand, as the position of the throttle will depend on the load on the engine at the time.

**Starting and Stopping Compound Corliss Engine.**—The operation of starting and stopping a compound Corliss engine is precisely similar to that of starting and stopping a simple Corliss engine. The high-pressure valve gear only is worked by hand in starting, the low-pressure eccentric hook having been hooked on previously. The low-pressure valve gear is worked by hand only while warming up the low-pressure cylinder. The directions given for operating the simple condensing engine apply to the condensing Corliss engine, so far as the treatment of the air pump, circulating pump, and condenser is concerned.

## POUNDING OF ENGINES

**Faulty Bearings.**—Loose journal brasses are the most frequent cause of pounding in engines. The remedy for pounding of this nature is obvious. The engine should be stopped and the brasses set up gradually until the pounding ceases. In the case of shaft journals, they may be set up without stopping the engine, provided the engineer can reach them without danger of being caught in the machinery.

It may so happen that the boxes or brasses are worn down until the edges of the upper half and those of the lower half are in contact and cannot be set up on the journal any farther; they are then said to be *brass and brass*, or *brassbound*. In a case of this kind, the journal must be *stripped*, as it is called, when the cap and brasses are removed from a journal. The edges of the brasses are then chipped or filed off, in order to allow them to be closed in.

It is a most excellent plan in practice to reduce the halves of the brasses so that they will stand off from each other when in place for a distance of $\frac{1}{8}$ to $\frac{1}{16}$ in. and to fill this space with hard sheet-brass liners from No. 20 to No. 22 Birmingham wire gauge in thickness, or even thinner. Should the journal become brass-bound, the cap may be slacked off and a pair of the liners slipped out without the necessity of stripping the journal.

In some instances journal-boxes are fitted with *keepers*, or *chipping pieces*, as they are sometimes called. These usually consist of cast-brass liners from $\frac{1}{4}$ to $\frac{1}{2}$ in. in thickness, having ribs or ridges cast on one side, for convenience of chipping and filing. These keepers are sometimes made of hardwood and are capable of being compressed slightly by the pressure exerted upon them during the setting-up process. When the boxes are babbitted, the body of the box is occasionally made of cast iron, in which case iron liners and keepers are used instead of brass ones.

In engines fitted with some types of friction couplings, there is a thrust exerted upon the shaft in the direction of its length. This will necessitate having a *thrust bearing*, or *thrust block*, as it is sometimes called. There are a number of types of thrust bearings, but the most common is the collar thrust, which

consists of a series of collars on the shaft that fit in corresponding depressions in the bearing. If these collars do not fit in the depressions rather snugly the shaft will have end play and there probably will be more or less pounding or backlash at every change of load on the engine. This can be remedied only by putting in a new thrust bearing and making a better fit with the shaft collars, unless the rings in the bearing are adjustable, in which case the end play may be taken up by adjusting the rings.

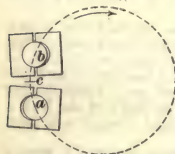
**Pounding in Cylinders.**—Pounding in the cylinders is frequently caused by water due to condensation or to that carried over from the boilers. This may be a warning that priming is likely to occur in the boilers or has already commenced. If the cylinders are not fitted with automatic relief valves, the drain cocks should be opened as quickly as possible and the throttle closed a little to check the priming.

Another source of pounding in the cylinder is a piston loose on the rod; this will result if the piston-rod nut or key backs off or the riveting becomes loose, permitting the piston to play back and forth on the piston rod. If due to backing off of the nut, the engine should be shut down instantly. There is generally very little room to spare between the piston-rod nut and the cylinder head; therefore, it cannot back off very far before it will strike and break the cylinder head. After the engine is stopped and the main stop-valve is closed, the cylinder head should be taken off and the piston nut set up as tightly as possible. As a measure of safety, a taper split pin should in all cases be fitted through the piston rod behind the nut or a setscrew should be fitted through the nut.

A slack follower plate or junk ring will cause pounding in the cylinder. It seldom happens that all the follower bolts back out at one time, but not infrequently one of them works itself out altogether. This is a very dangerous condition of affairs, especially in a horizontal engine. If the bolts should get end on between the piston and cylinder head, either the piston or the cylinder head is bound to be broken. Therefore, if there is any intimation that a follower bolt is adrift in the cylinder, the engine should be shut down instantly, the cylinder head taken off, the old bolt removed, and one having a tighter fit put in.

Broken packing rings and broken piston springs will cause noise in the cylinder, but it is more of a rattling than a pounding, and the sound will easily be recognized by the practiced ear. There is not so much danger of a breakdown from these causes as may be supposed, from the fact that the broken pieces are confined within the space between the follower plate and the piston flange.

Pounding in the cylinders of old engines is often produced by the striking of the piston against one or the other cylinder heads, due to the wearing away of the connecting-rod brasses. Keying up the brasses from time to time has the effect of lengthening or shortening the connecting-rod, depending on the design, and this change in length destroys the clearance at one end of the cylinder by an equal amount. The remedy is to restore the rod to its original length by placing sheet-metal liners behind the brasses; this obviously will move the piston back or ahead and restore the clearance. A rather rare cause of the piston striking the cylinder head is due to the unscrewing of the piston rod from the crosshead, in case it is fastened by a thread and check-nut. To obviate any danger, the check-nut should be tried frequently.

**Improper Valve Setting.**—The primary cause of another source of pounding is the improper setting of the steam valve, or possibly its improper design. In the case of improper setting of the valve, insufficient compression, insufficient lead, cut-off too early, and late release may all cause pounding on the centers.


**Reversal of Pressure.**—The effect of a reversal of pressure is clearly shown in the accompanying illustration. With the crankpin at $a$ and the engine running in the direction indicated by the arrow, the connecting-rod is subjected to a pull, but after the crankpin has passed the dead center $c$, the connecting-rod is subjected to a push, in which case the rear brass, as shown at $b$, bears against the crankpin, while in the former case, as shown at $a$, the front brass bears against the crankpin. By giving a sufficient amount of compression, the lost motion in the pins and journals is transferred gently from one side to the other before the crankpin reaches the dead center. If the compression is insufficient, there will be pounding.

**Insufficient Lead.**—Insufficient lead causes an engine to pound because the piston has then little or no cushion to impinge on as it approaches the end of its stroke, and it is brought to rest with a jerk. A similar effect will be produced by a late release; the pressure is retained too long on the driving side of the piston. The ideal condition is that the pressures shall be equal on both sides of the piston at a point in its travel just in advance of the opening of the steam port. The position of this point varies with the speed of the piston and other conditions that only the indicator card can reveal.

**Pounding at Crosshead.**—The crosshead is a source of pounding from various causes, of which the loosening of the piston rod is one of the most common. There are several methods of attaching the piston rod to the crosshead. The rod may pass through the crosshead with a shoulder or a taper, or both, on one side of the crosshead and a nut on the other; or the rod may be secured to the crosshead by a cotter, instead of the nut; or the end of the rod may be threaded and screwed into the crosshead, having a check-nut to hold the rod in place. In the case first mentioned, the nut may work loose, which will cause the crosshead to receive a violent blow, first, by the nut on one side and then by the shoulder or taper on the other, at each change of motion of the piston; the remedy is to set up the nut. A similar effect will be produced if the cotter should work loose and back out. In case the piston rod is screwed into the crosshead and the rod slacks back, the danger is that the piston will strike the rear cylinder head. The check-nut should be closely watched. Pounding at the crosshead may be due to loose wristpin brasses, in which case they should be set up, but not too tightly. In case a crosshead works between parallel guides, pounding may be caused if the crosshead is too loose between the guides, and the crosshead shoes should therefore be set out.

If pounding results from the wearing down of the shoe of a slipper crosshead, a liner should be put between the shoe and the foot of the crosshead or the shoe should be set out by the adjustment provided.

**Pounding in Air Pump.**—Pounding in the air pump is generally produced by the slamming of the valves, caused by an undue amount of water in the pump, which will usually relieve itself after a few strokes. The pump piston, however, may be loose on the piston rod or the piston rod may be loose in the crosshead. A broken valve may also cause pounding in the air pump, all of which must be repaired as soon as detected.

**Pounding in Circulating Pump.**—In a circulating pump of the reciprocating type, pounding may be caused by admitting too little injection water, and the pounding may be stopped by adjusting the injection valve to admit just the right quantity. It may so happen, however, that the injection water is very cold, and to admit enough of it to stop the pounding in the circulating pump will make the feedwater too cold. To meet this contingency, an air check-valve is often fitted to the circulating pump to admit air into the barrel of the pump as a cushion for the piston; this check-valve may be kept closed when not needed to admit air. A broken valve, a piston loose on its piston rod, and a piston rod loose in the crosshead will all cause pounding in the circulating pump; they should be treated in the same manner as was specified for similar troubles in the air pump.

## HOT BEARINGS

Should any of the bearings show an inclination to heat to an uncomfortable point when felt by the hand, the oil feed should be increased. If the bearing continues to get hotter, some flake graphite should be mixed with the oil and the mixture should be fed into the bearing through the oil holes, between the brasses, or wherever else it can be forced in.

If, after trying the remedies just mentioned, the bearing continues to grow hotter, to the extent, for instance, of scorching the hand or burning the oil, it indicates that the brasses have been expanded by the heat and that they are gripping the journal harder and harder the hotter they get. At this stage, if the engine is not stopped or if the heating is not checked, the condition of the bearing will continue to grow worse, and may become so bad as to slow down and eventually stop the engine by excessive friction. By this time the brasses and journal will be badly cut and in bad condition generally, and the engine must be laid up for repairs.

After the simple remedies previously given have been tried and failed to produce the desired results, the engine should be stopped and the cap or key of the hot bearing should be slacked back and the engine allowed to stand until the bearing has cooled off. If necessary, the cooling may be hastened by pouring cold water on the bearing, though this is objectionable, as it may

cause the brasses to warp or crack. Putting water on a very hot bearing should be resorted to only in an emergency, that is, when an engine must be kept running. Water may be used on a moderately hot bearing without doing very much harm. It is quite common in practice, when sprinklers are fitted to an engine, to run a light spray of water on the crankpins when they show a tendency to heat, with very beneficial results.

**Dangerous Heating.**—Should a bearing become so hot as to scorch the hand or to burn the oil before it is discovered it is imperative that the engine should be stopped, at least long enough to loosen up the brasses, even though it is necessary to start up again immediately; otherwise the brasses will be damaged beyond repair and deep grooves will be cut into the bearing. If the brasses are babbitted, the white metal will melt out of the bearing at this stage. The engine will then be disabled, and if there is not a spare set of brasses on hand, it will be inoperative until the old brasses are rebabbitted or until a new set is made and fitted.

If it is absolutely necessary in an emergency to keep the engine running while a bearing is very hot, the engineer must exercise his best judgment as to how he shall proceed. After slacking off the brasses, about the best he can do is deluge the inside of the bearing with a mixture of oil and graphite, sulphur, soapstone, etc., and the outside with cold water from buckets, sprinklers, or hose, taking the chances of ruining the brasses and cutting the journal.

**Refitting Cut Bearing.**—The wearing surfaces of the brasses and journal must be smoothed off as well as circumstances will permit; but if the grooves are very deeply cut, it will be useless to attempt to work them out entirely, and if the brasses are very much warped or badly cracked, it will be best to put in spare ones, if any are on hand. If not, the old ones must be refitted and used until a new set can be procured. As for the journal, it is permanently damaged. Temporary repairs can be made by smoothing down the journal and brasses; but at the first opportunity the journal should be turned in a lathe and the brasses properly refitted or replaced with new ones.

**Newly Fitted Bearings.**—The bearings of new engines are particularly liable to heat, as the wearing surfaces of the brasses and journal have just been machined and hence are comparatively rough. The conditions just mentioned also exist with new brasses and the journals of an old engine. If a new engine, or one with new brasses is run moderately, in regard to both speed and load, and with rather loose brasses, there will be little danger of hot bearings, provided proper attention is given to adjustment and lubrication. This is what is familiarly termed *wearing down the bearings.*

**Faulty Brasses.**—When the brasses of an engine bearing are set up too tight, heating is inevitable. Often, an attempt is made to stop a pound in an engine by setting up the brasses when the thump should be stopped in some other way. The brasses should be slacked off as soon as possible. As a matter of fact, hot bearings should never occur from this cause.

Bearings may heat because the brasses are too loose. The heating is caused by the hammering of the journal against the brasses when the crankpin is passing the dead centers. The derangement is easily remedied, however, by setting up the cap nuts or the key. Most engineers have their own views regarding the setting up of bearings. One method is to set up the cap nuts or key nearly solid and then slack them back half way; if the brasses are still too loose, they are set up again and slacked back less than before, repeating this operation until there is neither thumping nor heating.

Another method of setting up journal brasses is to fill up the spaces between the brasses with thin metal liners, from No. 18 to No. 22 Birmingham wire gauge in thickness, and a few paper liners for fine adjustment. Enough of these should be put in to cause the brasses to set rather loosely on the journal when the cap nuts or keys are set up solid. The engine should be run for a while in that condition; then a pair of the liners should be removed and the brasses set up solid again. This operation should be repeated until there is neither thumping nor heating. It may require a week or more, and with a large engine longer, to reach the desired point. If this system is carefully carried out, there will be very little danger of heating. In removing the liners, great care should be exercised not to disturb the brasses any more than is absolutely necessary.

Warped and cracked brasses will cause heating, because they do not bear evenly on the journal, and hence the friction is not distributed evenly over the entire surface. If the distortion is not too great, the brasses may be refitted to the journal by chipping, filing, and scraping; but if they are twisted so much that they cannot be refitted, nothing will do but new brasses.

Brasses and journals that have been hot enough to be cut and grooved are liable to heat up again any time on account of the roughness of the wearing surfaces. As long as the grooves in the journal are parallel and match the grooves in the brasses, the friction is not greatly increased; but if a smooth journal is placed between brasses that are grooved and pressure is applied, the journal crushes the grooves in the brasses and becomes brazed or coated with brass, and then heating results. The way to prevent heating from this cause is to work the grooves out of the journal and brasses by filing and scraping as soon as possible after they occur.

Faulty workmanship is a common cause of the heating of crankpins, wrist-pins, and bearings. The brasses in that case do not bear fairly and squarely, even though they appear all right to the eye. A crankpin brass must fit squarely on the end of the connecting-rod and the rod itself must be square. If the key, when driven, forces the brasses to one side or the other and twists the strap on the rod, it will draw the brasses slantwise on the pin and make them bear harder on one side than on the other, thus reducing the area of the bearing surfaces. The same is true of the shaft bearings. If the brasses do not bed fairly on the bottom of the pillow-block casting or do not go down evenly, without springing in any way, heating will result

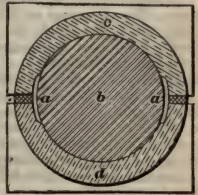
If the brasses are too long and bear against the collars of the journal when cold, they will most surely heat after the engine has been running a while. It is hardly possible to run bearings stone cold. They will warm up a little and the brasses will be expanded thereby, which will cause them to bear still harder against the collars. This, in turn, will induce greater friction and more expansion of the brasses. The evil may be obviated by chipping or filing a little off each end of the brasses until they cease to bear against the collars while running. A little side play is a good thing because it also promotes a better distribution of the oil and prevents the journal and brasses from wearing into concentric parallel grooves.

**Edges of Brasses Pinching Journal.**—Brasses, when first heated by abnormal friction, tend to expand along the surface in contact with the journal; this would open the brass and make the bore of larger diameter were it not prevented by the cooler part near the outside and by the bedplate itself. If the brass has become hot quickly and excessively, the resistance to expansion produces a permanent set on the layers of metal near the journal, so that on cooling, the brass closes and grips the journal. This is why some bearings always run a trifle warm and will not work cool. A continuance of heating and cooling will set up a bending action at the middle of the brass, which must eventually end in cracking it. Heating produced in this way may be prevented by chipping off the brasses at their edges parallel to the journal, as shown at *a* in the accompanying illustration, in which *b* is a section of the journal and *c* and *d* represent the top and bottom brasses, respectively.

**Hot Bearings Due to Faulty Oiling.**—It does not take long for a bearing to get very hot if it is deprived of oil. The two principal causes of dry bearings are an oil cup that has stopped feeding, either by reason of being empty or by being clogged up from dirt in the oil, and oil holes and oil grooves stopped up with dirt and gum.

The effect produced upon a bearing by an insufficient oil supply is similar to that of no oil, but in a less degree. Of course, it will take longer for a bearing to heat with insufficient oil than with none at all, and the engineer has more time in which to discover and remedy the difficulty.

Oils that contain dirt and grit are prolific sources of hot bearings. There is a great deal of dirt in lubricating oils of the average quality; therefore, all oil should be strained through a cloth or filtered, no matter how clear it looks. All oil cups, oil cans, and oil tubes and channels should be cleaned out frequently. Oil may be removed from the cups by means of an oil syringe, and all oil removed from the cups and cans should be strained or filtered before being used.

There are on the market many lubricating oils whose quality cannot be definitely decided on without an actual trial, and it is difficult to avoid getting a bad lot of oil sometimes. About the only safe way to meet this trouble is to pay a fair price to a reputable dealer for oil that is known to be of good quality, unless the purchaser is expert in judging oils or is able to pay a competent chemist to test them.


Bearings carrying very heavy shafts sometimes refuse to take the oil; or, if they do, it is squeezed out at the ends of the brasses or through the oil holes, and then the journal will run dry and heat. Large journals require oil of a high degree of viscosity, or heavy oil, as it is popularly called. Oil of this character has more difficulty in working its way under a heavy shaft than a thin oil has, but thin oil has not the body necessary to lubricate a large journal.

This difficulty may be met by chipping oil grooves or channels in the brasses. A round-nosed cape chisel, slightly curved, is generally used for this purpose; care should be taken to smooth off the burrs made by the chisel, which may be done with a steel scraper or the point of a flat file. The grooves are usually cut into the brass in the form of a **V** if the engine is required to run in only one direction; if it is to run in both directions the grooves should form an **X**. In the first instance, care must be taken that the **V** opens in the direction of rotation of the shaft; that is, the grooves should spread out from their junction in the same direction as that in which the journal turns. The oil grooves may be about $\frac{1}{4}$ in. wide and $\frac{1}{8}$ in. deep, and semicircular in cross-section.

**Grit in Bearings.**—Grit is an ever-present source of heating of bearings, and only by persistent effort can the engineer keep machinery running cool in a dirty atmosphere. The machinery of coal breakers, stone crushers, and kindred industries is especially liable to be affected in this way. Work done on a floor over an engine shakes dirt down upon it at some time or other; hence, all floors over engines should be made dust-proof by laying paper between the planks. If the engine room and firerooms communicate, and piles of red-hot clinkers and ashes are deluged with buckets of water, the water is instantly converted into a large volume of steam, carrying with it small particles of ashes and grit that penetrate into every nook and cranny, and these will find their way into the bearings sooner or later. Hot clinkers and ashes should be sprinkled, and the fireroom door should be closed while the ashes and clinkers are being hauled or wet down or while the fires are being cleaned or hauled. As an additional precaution, all open oil holes should be plugged with wooden plugs or bits of clean cotton waste as soon as possible after the engine is stopped, and should be kept closed until ready to oil the engine again preparatory to starting up. Plaited hemp or cotton gaskets should also be laid over the crevices between the ends of the brasses and the collars of the journals of every bearing on the engine and kept there while the engine is standing still.

**Overloading of Engine.**—The effects produced by overloading an engine are: The pressure on the brasses is increased to a point beyond that for which they were designed, the friction exceeds the practical limit, and the bearing heats. In case an engine is run at or near its limit of endurance, or if the journals are too small, it is wise and economical to have a complete set of spare brasses on hand ready to slip in when the necessity arises.

**Engine Out of Line.**—If the engine is not in line, the brasses do not bear fairly upon the journals. This will reduce the area of the bearing surfaces in contact to such an extent as to cause heating. If the engine is not very much out of line, matters may be considerably improved by refitting the brasses by filing and scraping down the parts of those that bear most heavily on the journal. If this does not answer, the heating will continue until the engine is lined up.

The crosshead guides of an engine out of line are apt to heat. The guides may also heat from other causes; for instance, the gibs may be set up too much. The danger of hot guides may be very much lessened by chipping zigzag oil grooves in their wearing surfaces and by attaching to the crosshead oil wipers made of cotton lamp wicking arranged so as to dip into oil reservoirs at each end of the guides if they are horizontal, and at the lower end if they are vertical. These wipers will spread a film of oil over the guides at every stroke of the crosshead.

**Effect of External Heat on Bearings.**—Bearings may get hot by the application of external heat. This may be the case if the engine is placed too near furnaces or an uncovered boiler, or in an atmosphere heated by uncovered steam pipes or other means. The excessive heat of the atmosphere will then expand the brasses until they nip the journals, which will generate additional heat and cause further expansion of the brasses, and so on until a hot bearing is the result. The remedy obviously depends upon the conditions of each case.

**Springing of Bedplate.**—If the bedplate of an engine is not rigid enough to resist the vibration of the moving parts, or if it is sprung by uneven settling or the instability of the foundation, the engine will be thrown out of line intermittently or permanently, and the bearings will heat. But it will do no good to refit the brasses unless the engine bed is stiffened in some way and leveled up.

**Springing or Shifting of Pillow-Block.**—The effect of the springing or shifting of the pedestal or pillow-block is similar to the springing of the engine bed; that is, the bearing will be thrown out of line, with the consequent danger of heating. As the pedestal is usually adjustable, it is an easy matter to readjust it, after which the holding-down bolts should be screwed down hard. If a pedestal is not stiff enough to resist the strains upon it and it springs, measures should be taken to stiffen it.

# STEAM TURBINES

The *turbine* is a machine by which the energy of a moving fluid, as steam or water, is transformed, producing a rotary motion. The rotating part of the turbine is cylindrical in form, comprising a shaft carrying a wheel, to which are fastened blades, also called *vanes* or *buckets*, against which the moving fluid impinges. This wheel, known as a *turbine wheel*, is enclosed in a casing. This form of motor is growing in popularity particularly in electrical work, the motor and generator being keyed on the same shaft, and for the following reasons:

1. The ability to use highly superheated steam, resulting in greater economy.

2. Reduced cost per unit capacity of the electrical generator, because of increased speed and less weight per horsepower.

3. Reduced floor space, resulting in less cost for land and power-station building.

4. Reduced cost of lubrication, as no cylinder oil is required and less oil is needed for bearings.

5. Saving in labor; engine oilers are not required, and one engineer can attend to more output than on reciprocating engines.

6. Reduced cost of foundations, as the turbine is balanced and has no reciprocating parts.

7. The turbine gives good steam economy over a wider range of load than the reciprocating engine; this is an important advantage in favor of the turbine, particularly for electric power stations where the load is variable. If it becomes necessary to operate a turbine unit at a comparatively light load, say, one-fourth or one-half load, the increase in steam consumption per horsepower per hour is not so great as it would be with a reciprocating engine under the same conditions. Also, a turbine unit will work more efficiently on overloads. The forces acting on the turbine wheels are continuous; hence, a uniform rotary motion is secured without the necessity of heavy flywheels.

**Types of Turbines.**—Steam turbines are of two general types, velocity turbines and pressure turbines. In the *velocity*, or *impulse, turbine* the rotation is produced by the direct impact or blow upon the blades of the turbine of steam issuing from a nozzle at high velocity, the action being the same as that of water in impulse water-wheels. Leading examples of this type of turbine are the De Laval, which is a *single-stage, expansion, velocity turbine*, in which all the expansion of the steam takes place in a single stage in one set of nozzles; the Curtis turbine, which is a *few-stage, expansion, velocity turbine*, in which the steam is expanded in two, three, four, or five stages; the Rateau turbine, which is a *multistage, expansion, velocity turbine*, in which the steam is expanded in many stages.

In the *pressure*, or *reaction, turbine*, the steam enters the central space and flows out through a series of guide vanes and then through the vanes of the moving wheel. In this type of wheel, the blades run full of steam, and there is a continual fall of pressure from the entrance of the steam until it leaves the turbine. The pressure turbine is always a multistage expansion turbine, the number of stages reaching 50 or 100. The leading American example is the Westinghouse-Parsons turbine.

When referring to the various stages of expansion in a turbine, it is customary to omit the term expansion and speak of the single-stage velocity turbine (instead of the single-stage expansion velocity turbine); the few-stage velocity turbine; the multistage velocity turbine.

In the turbines named, the Curtis turbine has a vertical shaft around which the blades rotate in a horizontal plane. In all the others the axis is horizontal and the blades rotate in vertical planes.

**Steam Consumption.**—The relation between the brake horsepower of the steam turbine at full load and the steam consumption is shown in the following table. The values in this table are taken from published tests of steam turbines that have attained the greatest commercial success. The turbines used saturated steam at from 115 to 140 lb. per sq. in., gauge pressure, and exhausted

into a vacuum of from 26 to 28.5 in. of mercury. Better results than those noted in the table can be obtained by the use of highly superheated steam.

The better the vacuum, the greater is the economy in the use of steam, both in the steam engine and in the steam turbine. A high vacuum is of greater value to the turbine, however, because the turbine can take advantage of a greater range of expansion. The degree of vacuum to be carried is a matter of dollars and cents; that is, it may cost more to create and maintain a high vacuum than may be saved in steam consumption. In a comparative test of a turbine and a triple-expansion engine under like conditions, it was found that, in the case of the reciprocating engine, little or nothing was to be gained by carrying a greater vacuum than about 26 in.; but the economy of the turbine in the use of steam increased rapidly as the vacuum was increased above 26 in. The conclusion is that high degrees of vacuum are more desirable for turbines than for engines.

**Comparison of Turbines and Engines.**—If the matter of steam consumption alone is considered, the average condensing turbine of less than about 700 H. P. is not so economical as the average compound or triple-expansion condensing engine, although the turbine may be preferred to the engine for other reasons. In larger sizes, however, and particularly in very large units, the economy of the turbine is very noticeable. The turbine possesses the ability to expand the steam to the lowest available condenser pressure without difficulty; but to do this in a reciprocating engine would require very

### STEAM CONSUMPTION PER HOUR OF TURBINES

| Brake Horsepower | Pounds of Steam Used | Brake Horsepower | Pounds of Steam Used |
|---|---|---|---|
| 100 | 18.2 | 600 | 15.3 |
| 200 | 17.5 | 700 | 14.8 |
| 300 | 16.9 | 800 | 14.3 |
| 400 | 16.3 | 900 | 13.7 |
| 500 | 15.8 | 1,000 | 13.2 |

large valves, and ports and heavy pistons, because of the great volume of steam to be handled at very low pressures.

**Finding Horsepower of Turbines.**—There is no way of finding the indicated horsepower of a steam turbine, because no form of indicator applicable to the turbine has been invented. Nor is any such instrument likely to be developed, owing to the very great difficulty of determining the energy given up to the blades of a turbine from a jet of steam. The usual way of finding the power of a steam turbine is to use a brake or a dynamometer and thus to determine the brake horsepower, or else to connect an electric generator to the turbine and measure the electrical output at the switchboard. In case the latter method is used, the efficiency of the generator and the turbine together is involved.

**Turbine Troubles.**—To obtain free running, it is necessary to allow clearance between the stationary and the moving rows of blades, as well as between the ends of the blades and the casing or the rotor. In impulse turbines, such as the Curtis and the Rateau, the clearance between the rows of blades is important; however, if it is made no greater than is necessary for mechanical reasons, the efficiency will not be affected seriously. In the reaction turbine, such as the Parsons, the clearance between the rows is of small consequence as compared with the clearance between the ends of the stationary blades and the rotor and between the ends of the moving blades and the casing. The former may vary from $\frac{1}{8}$ to 1 in. or more from the high-pressure to the low-pressure stage; but the tip clearance must be kept between a few hundredths and a few thousandths of an inch.

The stripping of the blades is one of the troubles to which turbines are subject. It may be due to the interference of the stationary and the movable blades, or to the rubbing of the blades against the shell or the rotor. In either of these cases the existing clearances are reduced by wear of the parts, shifting of the rotor, or unequal expansion of the rotor and the casing, until the blades touch and tear one another loose. The same result will occur if some foreign solid, as a stray nut or bolt, is carried along with the steam into the turbine. If a turbine is started too quickly, without being properly warmed up, the

sudden unequal expansion set up in the heavy casing and the lighter rotor may cause the blades to come in contact and be stripped. Stripping is claimed by some engineers to be more common in turbines in which the blades are not supported at their outer ends. To prevent it, some manufacturers apply shroud rings and metal lacings to the outer ends of the blades.

As there are no valves, pistons, or piston rings in the turbine to be maintained free from leakage, about the only thing that can affect the steam consumption is the condition of the blades. The blades of steam turbines are subjected to the cutting action of steam flowing at high velocities, and often carrying water particles with it. This cutting, or erosion, wears away the edges and surfaces of the blades. From the data available, it appears that the erosion is very slight if the steam is dry or superheated, no matter what velocities are used; but if the steam is wet, erosion will take place, and it will be greatly increased if the velocity of the steam is high. The horsepower is not affected to any great extent by blade erosion, according to the results of experience. In the case of a 100-H. P. De Laval turbine, the steam inlet edges of the blades were worn away about $\frac{1}{16}$ in., yet the steam consumption was only about 5% above that with new blades.

If the boiler supplying steam to a reciprocating engine primes badly, a slug of water may be carried over into the cylinder, resulting in a cracked piston or cylinder, a buckled piston rod or connecting-rod, or a wrecked frame. In case a steam turbine is used, however, the danger is greatly lessened. In turbines in which the blades are not supported at their outer ends, the water may cause stripping of the blades; but this is not very likely, as the blades at the high-pressure end of the turbine are short. A rush of water from the boiler has been known to bring a turbine almost to a stop without damaging the blades.

On account of the high speeds attained in turbine practice, the rotors are balanced accurately, so as to reduce vibration. But in spite of this careful balancing, vibration may manifest itself during ordinary running. It may be caused in any one of several ways, but the fundamental cause is lack of balance. If the rotor is warmed up too rapidly, the shaft or the wheels may be warped by unequal expansion, producing an unbalanced effect. The stripping of a blade or two will affect the balance of the wheel and tend to produce vibration. Even water carried into the turbine with the steam will bring about an unbalanced condition and will lead to vibration. When vibration is observed, it is well to reduce the speed a little, and to note whether this causes the vibration to cease. If it does, but comes back again as soon as the speed is increased, the source of the trouble should at once be determined.

**Operation of Turbines.**—If the steam turbine is a new one, or if it has been standing idle for a long period, it should not be started until it, together with its auxiliary apparatus, has been thoroughly inspected. The bearings should be properly adjusted and freed from dirt, and the entire lubricating system should be clean and filled with clean oil. The steam pipe from the boilers should be blown through, so as to clear it of any foreign matter that could be carried into the turbine by the steam. The governor mechanism should be examined, to see that it is in good order; the oil pump should be looked after, to ascertain whether it is in condition to maintain a continuous supply of oil; and, finally, before the turbine is started, the shaft should be turned over by hand, to insure that the rotor will turn freely in the casing.

A steam turbine should be started slowly, and before it is allowed to turn over under steam it should be warmed up. This is accomplished by opening the throttle valve just enough to let steam flow into the turbine. The drains should be kept open until the turbine is well started. The length of time required for warming up depends on the size of the turbine, a large unit requiring more time than a small one. As the warming up proceeds, the throttle may gradually be opened and the auxiliary machinery may be started. Once it has been started, the turbine should be brought up to speed slowly. If it is speeded up too rapidly, vibration will result. After the normal running speed has been reached, the load may be thrown on; but this, also, should be done gradually, to prevent a rush of water from the boiler with the steam.

If superheated steam is used, extra caution must be employed in starting, for during the warming up, with the throttle valve only slightly opened, the passing steam will be cooled considerably. But when the valve is opened wider, the greater volume passing will not lose so much of its superheat, and if care is not exercised the turbine will be subjected to sudden expansion because of the higher temperature of the steam. The main point in starting is to avoid any sudden changes of temperature in the turbine. If a turbine must be ready to be put in operation at short notice, steam may be allowed to flow

through it continually, by means of a by-pass around the throttle valve. It will always be warmed up, then, and can be brought up to speed with less danger and more rapidly.

The shaft or spindle of a turbine rotates at high speed, and therefore the bearings should be kept well lubricated; for if the oil supply fails, or if a bearing begins to heat because of grit carried into it, the resulting trouble will come very quickly. The presence of a hot bearing will usually be evidenced by the smell of burning oil or by the appearance of white smoke. When these signs are observed the oil supply should immediately be increased to the greatest possible amount. If this does not reduce the temperature of the bearing or prevent its further heating, the turbine should be shut down. To continue will result in burning out the bearing, and it is better to stop before this happens. The high speed of the shaft renders it impossible to nurse a hot turbine bearing as is done frequently in the running of reciprocating engines.

When shutting down a steam turbine, the throttle valve should be closed partly before the load is reduced, so as to prevent any possibility of racing when the load is finally taken off. The load may then be used as a brake to bring the rotor to a stop. When the throttle valve has been closed and the steam supply has been shut off completely, the auxiliary machinery may be stopped. If the load is taken off before the throttle is wholly closed the turbine may continue to rotate for $\frac{1}{2}$ hr., as the rotor is then running in a vacuum and under no load. The speed may be reduced by opening the drains and allowing air to enter the casing. The oil supply to the bearings must be continued until the turbine has come to rest, and the oil pump should be the last auxiliary to be stopped.

**Economy of Turbine.**—As there are no internal rubbing surfaces in the steam turbine, superheated steam may be employed without causing any of the lubrication troubles attending its use in reciprocating engines. Because of the greater amount of heat contained in 1 lb. of superheated steam, the economy of a turbine working with superheated steam is greater than that of one working with saturated steam; also, the efficiency is increased because the superheated steam causes less frictional resistance to the motion of the blades. To show the value of superheated steam in turbine work, it may be stated that 50° F. of superheat reduces the steam consumption about 6%; 100° F. of superheat reduces it about 10%; and 150° F. of superheat reduces it about 13½%. The use of high superheat, however, produces expansion of the rotor and the casing and may cause the blades to interfere; as a result, the usual degree of superheat in steam-turbine practice is 100° F., and seldom exceeds 150° F.

The steam turbine shows better economy than the steam engine when working with low-pressure steam in connection with a high vacuum; but when working with high-pressure steam and a vacuum of about 26 in., the engine is the more economical. As a consequence, a combination of the steam engine and the steam turbine has been adopted. The engine uses the high-pressure steam from the boilers and expands it to about atmospheric pressure. This exhaust steam then passes into the turbine, which exhausts into a condenser carrying a high degree of vacuum, and the expansion is carried to the extreme practicable limit. The turbine thus used in connection with an engine is termed an *exhaust-steam turbine.*

As the economy of the steam turbine is dependent so largely on the degree of vacuum carried, it is necessary for the engineer to watch the vacuum gauge closely. With reciprocating engines, the loss of 1 or 2 in. of vacuum may not be of much consequence; but in a turbine plant, where the vacuum is from 27 to 28 in., a loss of 1 or 2 in. will result in a considerable increase in the steam consumption. Because of the high vacuum employed, the difficulty of keeping pipes, valves, and glands from leaking is greater in turbine practice than in engine practice, but the greater economy obtained by keeping everything tight overbalances the increased care and labor.

**Care of Gears in De Laval Turbines.**—The De Laval Steam Turbine Company in their directions for operating their turbines state that in order to keep the gears in good condition the teeth should be cleaned occasionally when the turbine is not in service. They recommend that a wire brush and kerosene be employed for this purpose. At the same time the gear-case should also be thoroughly cleaned, and after the cleaning the gears should be well lubricated.

Should an engineer for any reason desire to take the gears out of the case, it is recommended that he secure special directions relating to their removal from the manufacturers. The same statement also applies to the adjustment of the gears, which need to be kept in perfect adjustment.

# RULES FOR STATIONARY ENGINEERS

If a gauge glass breaks turn off the water first and then the steam, to avoid scalding yourself.

Don't buy oil or waste simply because it is very cheap; it will cost more than a good article in the end.

When cutting rubber for gaskets, etc., have a dish of water handy, and keep wetting the knife blade; it makes the work much easier.

Don't forget that there is no economy in employing a poor fireman; he can, and probably will, waste more coal than would pay the wages of a first-class man.

An ordinary steam engine having two cylinders connected at right angles on the same shaft consumes one-third more steam than a single-cylinder engine, while developing only the same amount of power.

A fusible plug ought to be renewed every 3 mo., by removing the old metal and refilling the case; and it should be scraped clean and bright on both ends every time that the boiler is washed out, to keep it in good working order.

When trying a gauge-cock, don't jerk it open suddenly, for if the water happens to be a trifle below the cock, the sudden relief from pressure at that point may cause it to lift and flow out, thus showing a wrong height. Whereas, if it is opened quietly, no lift will occur, and it will show whether there is water or steam at that level.

Always open steam stop-valves between boilers very gently, that they may heat and expand gradually; by suddenly turning on steam a stop-valve chest was burst, due to the expansive power of heat unequally applied. The same care must be exercised when shutting off stop-valves; explosions have been caused by shutting a communicating stop-valve too suddenly—due to the recoil.

In order to obtain the driest possible steam from a boiler, there should be an internal perforated pipe (dry pipe, so called) fixed near the top of the boiler, and suitably connected to the steam pipe. The perforations in this pipe should be from one-quarter to one-half greater in area than that of the steam pipe.

If a glass gauge tube is too long, wet a triangular file with turpentine, then holding the tube in the left hand, with the thumb and forefinger at the place where it is to be cut, saw it quickly and lightly two or three times with the edge of the file. Take the tube in both hands, both thumbs being on the side opposite the mark, and 1 in. or so apart, and then try to bend the glass, using the thumbs as fulcrums, and it will break at the mark, which has weakened the tube.

A stiff charge of coal all over a furnace will lower the temperature 200° or 300° in a very short time. After the coal is well ignited the temperature will rise about 500°, and as it burns will gradually drop about 200°, until the fireman puts in another charge, when the sudden fall again takes place. This sudden contraction and expansion frequently causes the bursting of a boiler, and it is for this reason that light and frequent charges of coal, or else firing only one-half of the furnace at a time, should be always insisted on.

Be careful when using a wrench on hexagonal nuts that it fits snugly, or the edges of the nut will soon become rounded.

If a monkey-wrench is not placed on the nut properly, the strain will often bend or fracture the wrench.

The area of grate for a boiler should never be less than ⅓ sq. ft. per I. H. P. of the engine, and it is seldom advisable to increase this allowance beyond ½ sq. ft. per I. H. P.

The area of tube surface for a boiler should not be less than 2½ sq. ft. per I. H. P. of the engine.

The ratio of heating surface to grate area in a boiler should be 30 to 1 as a minimum, and may often be increased to 40 to 1, or even more, with advantage.

Lap-welded pipe of the same rated size has always the same outside diameter, whether common, extra, or double extra, but the internal diameter is of course decreased with the increased thickness.

A good cement for steam and water joints is made by taking 10 parts, by weight, of white lead, 3 parts of black oxide of manganese, 1 part of litharge, and mixing them to the proper consistency with boiled linseed oil.

To harden a cutting tool, heat it in a coke fire to a blood-red heat and plunge it into a solution of salt and water (1 lb. of salt to 1 gal. of water), then polish the tool, heat it over gas, or otherwise, until a dark straw and purple mixed color shows on the polish, and cool it in the salt water.

Small articles can be plated with brass by dipping them in a solution of 9¼ gr. each of sulphate of copper and chloride of tin, in 1¾ pt. of water.

Don't be eternally tinkering about an engine, but let well enough alone.

Don't forget that it is possible to drive a key with a copper hammer just as well as with a steel one, and that it doesn't leave any marks.

Keep on hand slips of thin sheet copper, brass, and tin, to use as liners, and if these are shaped properly, much time will be saved when they are needed.

A few wooden skewer pins, such as butchers use, are very useful for many purposes in an engine room.

In running a line of steam pipe where there are certain rigid points, make arrangements for expansion on the line between those points.

Arrange the usual work of the engine and firerooms systematically, and adhere to it.

Don't forget that cleanliness is next to godliness.

Rubber cloth kept on hand for joints should be rolled up and laid away by itself, as any oil or grease coming in contact with it will cause it to soften and give out when put to use.

When using a jet condenser, let the engine make three or four revolutions before opening the injection valve, and then open it gradually, letting the engine make several more revolutions before it is opened to the full amount.

Open the main stop-valve before the fires are started under the boilers.

When starting fires, don't forget to close the gauge-cocks and safety valve as soon as steam begins to form.

An old Turkish towel, cut in two lengthwise, is better than cotton waste for cleaning brass work.

Always connect the steam valves in such a manner that the valve closes against the constant steam pressure.

Turpentine well mixed with black varnish makes a good coating for iron smoke pipes.

Ordinary lubricating oils are not suitable for use in preventing rust.

It is possible to make a hole through glass by covering it with a thin coating of wax, warming the glass and spreading the wax on it; then scrape off the wax where the hole is wanted, drop a little fluoric acid on the spot with a wire. The acid will cut a hole through the glass, and it can be shaped with a copper wire covered with oil and rottenstone.

A mixture of 1 oz. of sulphate of copper, $\frac{1}{4}$ oz. of alum, $\frac{1}{2}$ teaspoonful of powdered salt, 1 gill of vinegar and 20 drops of nitric acid will make a hole in steel that is too hard to cut or file easily. Also, if applied to steel and washed off quickly, it will give the metal a beautiful frosted appearance.

# COMPRESSED AIR

---

## CLASSIFICATION AND CONSTRUCTION OF COMPRESSORS

An *air compressor* consists essentially of a cylinder in which atmospheric air is compressed by a piston, the driving power being steam, water, oil, gas, or electricity. Steam-driven compressors in ordinary use may be classed as follows:

1. *Straight-line* type, in which a single horizontal air cylinder is set tandem with its steam cylinder, and provided with two flywheels; this pattern is generally adapted for compressors of small size.

2. *Duplex* type, in which there are two steam cylinders, each driving an air cylinder, and coupled at 90° to a crank-shaft carrying a flywheel.

3. *Horizontal, cross-compound* engines, each steam cylinder set tandem with an air cylinder, as in 2.

4. *Vertical, simple,* or *compound* engines, with the air cylinders set above the steam cylinders.

5. *Compound* or *stage compressors*, in which the air cylinders themselves are compounded; the compression is carried to a certain point in one cylinder and successively raised and finally completed to the desired pressure in the others. They may be either of the straight-line or duplex form, with simple or compound steam cylinders. The principle of compound, or two-stage, air compression is recognized as applicable for even the moderate pressures required in mining. Compressors of class 5 are frequently employed, as well as classes 1, 2, and 3.

**Theory of Air Compression.**—The useful effect or efficiency of a compressor is the ratio of the force stored in the compressed air to the work that has been expended in compressing it; this probably never reaches 80% and often falls below 60%.

*Free Air* is air at ordinary atmospheric pressure as taken into the compressor cylinder; as commonly used, this means air at sea-level pressure (14.7 lb. per sq. in.) at 60° F. The *absolute pressure* of air is measured from zero, and is equal to the assumed atmospheric pressure plus gauge pressure. Air-compression calculations depend on the two well-known laws:

1. *Boyle's Law.*—The temperature being constant, the volume varies inversely as the pressure; or $PV = P'V' = $ a constant; in which $V$ equals the volume of a given weight of air at the freezing point, and the pressure $P$; $V'$ equals the volume of the same weight of air at the same temperature and under the pressure $P'$.

2 *Gay-Lussac's Law.*—The volume of a gas under constant pressure, when heated, expands, for each degree of rise in temperature, by a constant proportional part of the volume that it occupied at the freezing point; or, $V' = V(1 + at°)$, in which $a$ equals $\frac{1}{273}$ for centigrade degrees, or $\frac{1}{461}$ for Fahrenheit degrees.

Theoretically, air may be compressed in two ways, as follows:

1. *Isothermally*, when the temperature is kept constant during compression, and in this case, the formula $PV = P'V'$ is true.

2. *Adiabatically*, when the temperature is allowed to rise without check during the compression.

As the pressure rises faster than the volume diminishes, the equation $PV = P'V'$ no longer holds, and $\frac{P'}{P} = \left(\frac{V}{V'}\right)^n$, in which $n$ equals 1.406. The specific heat of air at constant pressure is .2375, and at constant volume .1689, and $n = .2375 \div .1689 = 1.406$.

In practice, compression is neither isothermal nor adiabatic, but intermediate between the two. The values of $n$ for different conditions in practice as determined from a 2,000-H. P. stage compressor at Quai de la Gare, Paris, are as follows: For purely adiabatic compression, with no cooling arrangements, $n = 1.406$; in ordinary single-cylinder dry compressors, provided with a water-jacket, $n$ is roughly 1.3; while in the best wet compressors (with spray injection), $n$ becomes 1.2 to 1.25. In the poorest forms of compressor, the value $n = 1.4$ is closely approached. For large, well-designed compressors with compound air cylinders, the exponent $n$ may be as small as 1.15.

**Construction of Compressors.**—Compressors are usually built with a short stroke, as this is conducive to economy in compression as well as the attainment of a proper rotative speed. In ordinary single-stage compressors, the usual ratio of length of stroke to diameter of steam cylinders is $1\frac{1}{2}$ to 1 or $1\frac{1}{4}$ to 1. In some makes, such as the Rand, the ratio is considerably greater, varying from $1\frac{1}{2}$ to $1\frac{3}{4}$ to 1, as in several large plants built for the Calumet & Hecla Mining Co. Many compressors have length and diameter of steam cylinders equal. The relative diameters of the air and steam cylinders depend on the steam pressure carried, and the air pressure to be produced. In mining operations, there is usually but little variation in these conditions. For rock-drill work, the air pressure is generally from 60 to 80 lb.

In using water-power, a compressor is driven most conveniently by a bucket impact wheel, such as the Pelton or Knight. The waterwheel is generally mounted directly on the crank-shaft, without the use of gearing. As the power developed is uniform throughout the revolution of the wheel, the compressor should be of duplex form, in order to equalize the resistance so far as possible. The rim of the wheel is made extra heavy, to supply the place of a flywheel. When direct-connected, the wheel is of relatively large diameter, as its speed of rotation must of necessity be slow. With small high-speed wheels, the compressor cylinders may be operated through belting or gearing. In most cases, however, the waterwheel may be large enough to render gearing unnecessary. Impact wheels may be employed with quite small heads of water, by introducing multiple nozzles. To prevent the water from splashing over the compressor, the wheel is enclosed in a tight iron or wooden casing. The force of the water is regulated usually by an ordinary gate valve. If the head is great, it may be necessary to introduce means for deflecting the nozzle, so that, when the compressor is to be stopped suddenly, danger of rupturing the water main will be avoided.

**Rating of Compressors.**—Compressors are rated as follows: (1) In terms of the horsepower developed by the steam end of the compressor, as shown by

indicator cards taken when running at full speed and when the usual volume of air is being consumed; (2) compressors for mines are often rated roughly as furnishing sufficient air to operate a certain number of rock drills; a 3-in. drill requires a volume of air at 60 lb. pressure, equal to 100 or 110 cu. ft. of free atmospheric air per minute; (3) in terms of cubic feet of free air compressed per minute to a given pressure.

As the actual capacity of a compressor depends on the density of the intake air, it will be reduced when working at an altitude above sea level, because of the diminished density of the atmosphere. The accompanying table gives the percentages of output at different elevations.

## EFFICIENCIES OF AIR COMPRESSORS AT DIFFERENT ALTITUDES

| Altitude Feet | Barometer Pressure | | Volumetric Efficiency of Compressor Per Cent. | Loss of Capacity Per Cent. | Decreased Power Required Per Cent. |
|---|---|---|---|---|---|
| | Inches Mercury | Pounds per Square Inch | | | |
| 0 | 30.00 | 14.75 | 100 | 0 | 0 |
| 1,000 | 28.88 | 14.20 | 97 | 3 | 1.8 |
| 2,000 | 27.80 | 13.67 | 93 | 7 | 3.5 |
| 3,000 | 26.76 | 13.16 | 90 | 10 | 5.2 |
| 4,000 | 25.76 | 12.67 | 87 | 13 | 6.9 |
| 5,000 | 24.79 | 12.20 | 84 | 16 | 8.5 |
| 6,000 | 23.86 | 11.73 | 81 | 19 | 10.1 |
| 7,000 | 22.97 | 11.30 | 78 | 22 | 11.6 |
| 8,000 | 22.11 | 10.87 | 76 | 24 | 13.1 |
| 9,000 | 21.29 | 10.46 | 73 | 27 | 14.6 |
| 10,000 | 20.49 | 10.07 | 70 | 30 | 16.1 |
| 11,000 | 19.72 | 9.70 | 68 | 32 | 17.6 |
| 12,000 | 18.98 | 9.34 | 65 | 35 | 19.1 |
| 13,000 | 18.27 | 8.98 | 63 | 37 | 20.6 |
| 14,000 | 17.59 | 8.65 | 60 | 40 | 22.1 |
| 15,000 | 16.93 | 8.32 | 58 | 42 | 23.5 |

EXAMPLE.—Calculate the volume of air furnished by an $18'' \times 24''$ compressor working at an elevation of 5,000 ft. above sea level, making 95 rev. per min., and having a piston speed of 380 ft. per min.

SOLUTION.— $9^2 \times 3.14 = 254.3$ sq. in. = piston area. $\frac{254.3}{144} \times 380 = 668.8$ cu. ft. = volume displaced per minute by the piston; deducting 10% for loss gives 602 cu. ft. At sea level at 80 lb. gauge pressure, this equals $\frac{15}{80+15} \times 602 = 95$ cu. ft. At an elevation of 5,000 ft., the output of a compressor would be $95 \times 84\% = 79.8$ cu. ft. per min.

**Cooling.**—Compressor cylinders may be cooled by injecting water into the cylinder, in which case they are known as *wet compressors*; or by jacketing the cylinder in water, when they are known as *dry compressors*.

## TRANSMISSION OF AIR IN PIPES

The actual discharge capacity of piping is not proportional to the cross-sectional area alone, that is, to the square of the diameter. Although the periphery is directly proportional to the diameter, the interior surface resistance is much greater in a small pipe than in a large one, because, as the pipe becomes smaller, the ratio of perimeter to area increases.

To pass a given volume of compressed air, a 1-in. pipe of given length requires over three times as much head as a 2-in. pipe of the same length. The character of the pipe, also, and the condition of its inner surface, have much to do with the friction developed by the flow of air. Besides imperfections in the surface of the metal, the irregularities incident on coupling together the lengths of pipe must increase friction. There are so few reliable

data that the influences by which the values of some of the factors may be modified are not fully understood; and, owing to these uncertain conditions, the results obtained from formulas are only approximately correct.

Among the formulas in common use, perhaps the most satisfactory is that of D'Arcy. As adopted for compressed-air transmission, it takes the form:

$$D = c \sqrt{\frac{d^5(p_1 - p_2)}{w_1 l}}$$

in which $D$ = volume of compressed air discharged at final pressure in cubic feet per minute;

$c$ = coefficient varying with diameter of pipe, as determined by experiment;

$d$ = diameter of pipe in inches (actual diameters of $1\frac{1}{4}$- and $1\frac{1}{2}$-in. pipe are 1.38 in. and 1.61 in., respectively; nominal diameters of all other sizes may be taken for calculations);

$l$ = length of pipe, in feet;

$p_1$ = initial gauge pressure, in pounds per square inch;

$p_2$ = final gauge pressure, in pounds per square inch;

$w_1$ = density of air, or its weight at initial pressure $p_1$, in pounds per cubic foot.

The values of the coefficients $c$ for sizes of piping up to 12 in. are:

| | | |
|---|---|---|
| 1 in............45.3 | 5 in............59.0 | 9 in............61.0 |
| 2 in............52.6 | 6 in............59.8 | 10 in............61.2 |
| 3 in............56.5 | 7 in............60.3 | 11 in............61.8 |
| 4 in............58.0 | 8 in............60.7 | 12 in............62.0 |

Some apparent discrepancies exist for sizes larger than 9 in., but they cause no very material differences in the results.

Another formula, published by Mr. Frank Richards, is as follows:

$$H = \frac{V^2 L}{10,000 \, D^5 a}$$

in which $H$ = head or difference of pressure required to overcome friction and maintain flow of air;

$V$ = volume of compressed air delivered, in cubic feet per minute;

$L$ = length of pipe, in feet;

$D$ = diameter of pipe, in inches;

$a$ = coefficient, depending on size of pipe.

Values of $a$ for nominal diameters of wrought-iron pipe:

| | | |
|---|---|---|
| 1 in......... .350 | 3 in......... .730 | 8 in.........1.125 |
| $1\frac{1}{4}$ in......... .500 | $3\frac{1}{2}$ in......... .787 | 10 in.........1.200 |
| $1\frac{1}{2}$ in......... .662 | 4 in......... .840 | 12 in.........1.260 |
| 2 in......... .565 | 5 in......... .934 | |
| $2\frac{1}{2}$ in......... .650 | 6 in.........1.000 | |

The values of $a$ for $1\frac{1}{4}$ and $1\frac{1}{2}$ in. pipe are not consistent with those for other sizes, for the reason already stated. When using this formula with its constants, the calculated losses of pressure are found to be smaller, and, conversely, the volumes of air discharged are larger, under the same conditions than those obtained from D'Arcy's formula.

It must be remembered that, within certain limits, the loss of head or pressure increases with the square of the velocity. To obtain the best results, it has been found that the velocity of flow in the main air pipes should not exceed 20 or 25 ft. per sec. When the initial velocity much exceeds 50 ft. per sec., the percentage loss becomes very large; and, conversely, by using piping large enough to keep down the velocity, the friction loss may be almost eliminated. For example, at the Hoosac tunnel, in transmitting 875 cu. ft. per min. of free air at an initial pressure of 60 lb., through an 8-in. pipe, 7,150 ft. long, the average loss including leakage was only 2 lb. A volume of 500 cu. ft. per min. of free air, at 75 lb., can be transmitted through 1,000 ft. of 3-in. pipe with a loss of 4.1 lb., while if a 5-in. pipe is used the loss will be reduced to .24 lb. The velocity of flow in the latter case is only 10 ft. per sec.

When driving the Jeddo mining tunnel, at Ebervale, Pa., two $3\frac{1}{2}$-in. drills were used in each heading, with a 6-in. main, the maximum transmission distance being 10,800 ft. This pipe was so large in proportion to the volume of air required for the drills (230 cu. ft. per min. of free air) that the loss was reduced to an extremely small quantity. A calculation shows a loss of .002 lb., and the gauges at each end of the main were found to record practically the same pressure.

A due regard for economy in installation, however, must limit the use of very large piping, the cost of which should be considered in relation to the

cost of air compression in any given case.  Diameters of from 4 to 6 in. for the mains are large enough for any ordinary mining practice.  Up to a length of 3,000 ft., a 4-in. pipe will carry 480 cu. ft. per min. of free air compressed to 82 lb., with a loss of 2 lb. pressure.  This volume of air will run four 3-in. drills.  Under the same conditions, a 6-in. pipe, 5,000 ft. long, will carry 1,100 cu. ft. per min. of free air, or enough for 10 drills.

A mistake is often made by putting in branch pipes of too small a diameter.  For a distance of, say, 100 ft., a 1¼-in. pipe is small enough for a single drill, though a 1-in. pipe is frequently used.  While it is, of course, admissible to increase the velocity of flow in short branches considerably beyond 20 ft. per sec., extremes should be avoided.  To run a 3-in. drill from a 1-in. pipe 100 ft. long, will require a velocity of flow of about 55 ft. per sec., causing a loss of 10 lb. pressure.

The piping for conveying compressed air may be of cast or wrought iron.  If of wrought iron, as is customary, the lengths are connected either by sleeve couplings or by cast-iron flanges into which the ends of the pipe are screwed or expanded.  Sleeve couplings are used for all except the large sizes.  The smaller sizes, up to 1¼ in., are butt-welded, while all from 1½ in. up are lap-welded, to insure the necessary strength.  Wrought-iron, spiral-seam, riveted, or spiral-weld steel tubing is sometimes used.  It is made in lengths of 20 ft. or less.  For convenience of transport in remote regions, rolled sheets in short lengths may be had.  They are punched around the edges, ready for riveting, and are packed closely—four, six, or more sheets in a bundle.

All joints in air mains and branches should be carefully made.  Air leaks are more expensive than steam leaks because of the losses suffered when compressing the air.  The pipe may be tested from time to time by allowing the air at full pressure to remain in the pipe long enough to observe the gauge.  A leak should be traced and stopped immediately.  When putting together screw joints, care should be taken that none of the white lead or other cementing material is forced into the pipe; this would cause obstruction and increase the friction loss.  Also, each length as put in place should be cleaned thoroughly of all foreign substances that may have lodged inside.  To render the piping readily accessible for inspection and stoppage of leaks, it should, if buried, be carried in boxes sunk just below the surface of the ground; or, if underground, it should be supported upon brackets along the sides of the mine workings.  Low points in pipe lines, which would form pockets for the accumulation of entrained water, should be avoided, as they obstruct the passage of the air.  In long pipe lines, where a uniform grade is impracticable, provision may be made near the end for blowing out the water at intervals, when the air is to be used for pumps, hoists, or other stationary engines.

For long lengths of piping, expansion joints are required, particularly when on the surface.  They are not often necessary underground, as the temperature is usually nearly constant, except in shafts, or where there may be considerable variations of temperature between summer and winter.

## LOSSES IN THE TRANSMISSION OF COMPRESSED AIR

To obtain compressed air, an engine drives a compressor, which forces air into a reservoir; the air under pressure is led through pipes to the air engine, and is there used after the manner of steam.  The resulting power is frequently a small percentage of the power expended.  In a large number of cases the losses are due to poor designing, and are not chargeable as faults of the system or even to poor workmanship.

The losses are chargeable, first, to friction of the compressor.  This will amount ordinarily to 15% or 20%, and can be helped by good workmanship, but cannot probably be reduced below 10%.  Second, a loss is occasioned by pumping the air of the engine room, rather than air drawn from a cooler place; this loss varies with the season, and amounts to from 3% to 10% and can all be saved.  The third loss, or series of losses, is caused by insufficient supply, difficult discharge, defective cooling arrangements, poor lubrication, and a host of other causes, in the compression cylinder.  The fourth loss is found in the pipe, it varies with every different situation, and is subject to somewhat complex influences.  The fifth loss is chargeable to a fall of temperature in the cylinder of the air engine.  Losses arising from leaks are often serious, but the remedy is too evident to require demonstration; no leak can be so small as not to require immediate attention.  An attendant who is careless about packings and hose couplings will permit losses for which no amount of engineering skill can compensate.

It is possible to realize 100% efficiency in the air engine, leaving friction out of our consideration, only when the expansion of the air and the changes of its temperature in the expanding or air-engine cylinder are precisely the reverse of the changes that have taken place during the compression of the air in the compressing cylinder; but these conditions can never be realized. The air during compression becomes heated, and during expansion it becomes cold. If the air immediately after compression, before the loss of any heat, was used in an air engine and there perfectly expanded back to atmospheric pressure, it would, on being exhausted, have the same temperature it had before compression, and its efficiency would be 100%.

But the loss of heat after compression and before use cannot be prevented, as the air is exposed to such very large radiating surfaces in the reservoir and pipes, on its passage to the air engine. The heat that escapes in this way, did, while in the compressing cylinder, add much to the resistance of the air to compression, and as it is sure to escape, at some time, either in reservoir or pipes, the best plan is to remove it as fast as possible from the cylinder and thus remove one element of resistance. Hence, compressors are almost universally provided with cooling attachments more or less perfect in their action, the aim being to secure isothermal compression, or compression having equal temperature throughout.

If air compressed isothermally is used with perfect expansion and the fall of temperature during expansion is prevented, 100% efficiency will be obtained. But air will grow cold when expanded in an engine, hence warming attachments have the same economic place on an air engine that cooling attachments have on an air compressor. In fact, attachments of this kind are found in large and permanently located engines, but their use on most of the engines for mine work is dispensed with, and the engines expand the air adiabatically, or without receiving heat.

The practical engineer, therefore, has to deal with nearly isothermal compression, and nearly adiabatic expansion, and must also consider that the air in reservoirs and pipes becomes of the same temperature as surrounding objects. Consideration must also be had for the friction of the compressor and the air engine. For the pressure of 60 lb., which is that most commonly used, the decrease in resistance to compression secured by the cooling attachments is almost exactly equaled by the friction of the compressor. Hence it is safe, when calculating the efficiency of the air engine, to consider the compressor as being without cooling attachments, and also as working without friction. The results of such calculations will be too high efficiencies for light pressures, which are little used; about correct for medium pressures, which are commonly employed; and too low for higher pressures, and will thus have the advantage of not being overestimated. This result is occasioned by the fact that, owing to the slight heat in compressing low pressures of air, the saving of power by the cooling attachments is not equal to the friction of the machine, but at high pressures, on account of the great heat, the cooling attachments are of great value and save very much more power than friction consumes.

In expanding engines, the expansion never falls as low as the adiabatic law would indicate, owing to a number of reasons, but if the expansion is considered as adiabatic, an error in calculations caused thereby will be on the safe side and the actual power will exceed the calculated power. Therefore, the compressor and engine may be considered as following the adiabatic law of compression and expansion, and as working without friction.

With this view of the case, the efficiency of an air engine, working with perfect expansion, stated in percentages of the power required to operate the compressor, can be placed as here shown for the various pressures above the atmosphere. As the efficiencies for the lower pressures are very much greater than for the high pressures, the conclusion is almost irresistible that to secure economical results air engines should be designed to run with light pressures.

| Pressure Above Atmosphere Pounds | Efficiency Per Cent. |
|---|---|
| 2.9 | 94.85 |
| 14.7 | 81.79 |
| 29.4 | 72.72 |
| 44.1 | 66.90 |
| 58.8 | 62.70 |
| 73.5 | 59.48 |
| 88.2 | 56.88 |

In the foregoing the pipe friction has been entirely neglected. A pressure of 2.9 lb. is credited with an efficiency of 94.85%; but, if the air were conveyed through a pipe, and the length of the pipe and the velocity of flow were such that 2.9 lb. pressure was lost in friction, the efficiency of the air, instead of being 94.85%, would be absolutely zero. It is the power that can be obtained from the air, after it has passed the pipe and lost a part of its pressure by friction, that must be considered when the efficiency of an apparatus is given.

The foregoing table of efficiencies with a loss of 2.9 lb. in the pipe, now gives different values for the efficiencies at the various pressures.

| Pressure Above Atmosphere Pounds | Efficiency Per Cent. |
|---|---|
| 2.9 | 00.00 |
| 14.7 | 70.44 |
| 29.4 | 68.81 |
| 44.1 | 64.87 |
| 58.8 | 61.48 |
| 73.5 | 58.62 |
| 88.2 | 56.23 |

It will be noticed that the light pressures have lost most by the pipe friction, 2.9 lb. having lost 100%; 14.7 lb. 11%, and 88.2 lb. only a trifle over one-half of 1%. It is also seen now 14.7 lb. is apparently the economical pressure to use. But a further careful analysis of the subject shows, that when the loss in the pipe is 2.9 lbs., then 20.5 lb. is the most economical pressure to use, and that the efficiency is 71%. But 2.9 lb. is a very small loss between compressor and air engine, and cases are extremely exceptional where the friction of valves, pipes, elbows, ports, etc. does not far exceed this. Yet, with these conditions, which are very difficult to fill, 20.5 lb. is the lightest pressure that should probably ever be used for conveying power, and 71% is an efficiency scarcely to be obtained.

Continuing the investigation and taking examples where the pipe friction amounts to 5.8 lbs., it is found that the following efficiencies correspond to the stated pressure:

| Pressure Above Atmosphere Pounds | Efficiency Per Cent. |
|---|---|
| 14.7 | 57.14 |
| 29.4 | 64.49 |
| 44.1 | 62.71 |
| 58.8 | 60.12 |
| 73.5 | 57.73 |
| 88.2 | 55.59 |

As friction increases, or, in other words, when more air is used and greater demands are made on the carrying capacity of the pipe, the pressure must be greatly increased to attain the most economical results. If the demands are such as to increase the friction and loss in pipe to 14.7 lbs., the air of 14.7 lb. pressure at the compressor is entirely useless at the air engine. The table will therefore stand thus:

| Pressure Above Atmosphere Pounds | Efficiency Per Cent. |
|---|---|
| 14.7 | 00.00 |
| 29.4 | 48.53 |
| 44.1 | 55.13 |
| 58.8 | 55.64 |
| 73.5 | 54.74 |
| 88.2 | 53.44 |

It is to be noticed that 88.2 lb. pressure has lost only about 3½% of its efficiency by reason of as high a friction as 14.7 lb., while the efficiency of the lower pressures has been greatly affected. As the friction increases the most efficient, and consequently, most economical, pressure increases. In fact, for any given friction in a pipe, the pressure at the compressor must not be carried below a certain limit. The following table gives the lowest pressures that should be used at the compressor, with varying amounts of friction in the pipe:

| Friction Pounds | Pressure at Compressor Pounds | Efficiency Per Cent. |
|---|---|---|
| 2.9 | 20.5 | 70.92 |
| 5.8 | 29.4 | 64.49 |
| 8.8 | 38.2 | 60.64 |
| 11.7 | 47.0 | 57.87 |
| 14.7 | 52.8 | 55.73 |
| 17.6 | 61.7 | 53.98 |
| 20.5 | 70.5 | 52.52 |
| 23.5 | 76.4 | 51.26 |
| 26.4 | 82.3 | 50.17 |
| 29.4 | 88.2 | 49.19 |

So long as the friction of the pipe equals the amounts there given, an efficiency greater than the corresponding sums stated in the table cannot be expected. In a case that corresponds to any of those cited in the table, the efficiency can be increased only by reducing the friction. An increase in the size of pipe will reduce friction by reason of the lower velocity of flow required for the same amount of air. But many situations will not admit of large pipes being employed, owing to considerations of economy outside of the question of fuel or prime motor capacity.

An increase of pressure will decrease the bulk of air passing in the pipe, and in that proportion will reduce its velocity. This will decrease the loss by friction, and, as far as that goes, a gain is obtained, but there is a new loss, and that is the diminishing efficiencies of increasing pressures. Yet as each cubic foot of air is at a higher pressure, and, therefore, carries more power, as many cubic feet will not be needed for the same work. It is obvious that with so many sources of gain or loss the question of selecting the proper pressure is not to be decided hastily.

As an illustration of the combined effect of these different elements, a very common case will be taken. The compressor makes 102 rev. per min., pressure is 52.8 lb., loss in pipe is 14.7 lb., machine in mine running at 38.2 lb., efficiency is 55.73%. As long as the friction of the pipe amounts to 14.7 lb., 52.8 lb. is the best pressure and 55.73% the greatest efficiency, but friction may be reduced by reducing the bulk of air passing through the pipe and if the cylinder of the air engine is reduced until it requires 47 lb. pressure to do the same work as before; the friction of pipe will then drop to 11.7 lb. The pressure on the compressor will rise to 58.8 lb., its number of revolutions will fall to 100, and the resulting efficiency will be 57.22%.

Another change of pressure on compressor to 64.7 lb. will decrease its revolutions to 93, friction to 8.8 lb., and its efficiency will rise to 57.94%. If the pressure is increased to 73.5 lb., there will be only 84 revolutions of compressor, 5.8 lb. loss in pipe, and an efficiency of 57.73%. In this last case the efficiency begins to fall off a little, and higher pressures will show less efficiency; but, in comparison with the first example, the same work will be done with a trifle less power and with a decrease of nearly 20% in the speed of the compressor.

Other common examples can be shown where an increase of pressure would result in wonderful increase in efficiency and economy. There are many cases where light pressures and high velocity in the pipe will convey a given power with greater economy than higher air pressures and lower speed of flow through the pipe. But these cases arise mostly when the higher air pressures become very much greater than are at present in common use. Therefore, when estimating the efficiency of the complete outfit, it is found that the pipe and the pressure are very important elements, and must be determined with care and skill to secure the most satisfactory results. As the volume and power of air vary with its pressure, the size and consequent cost of compressor for a certain work will also be affected by the pressure. To plan an outfit for a mine, due regard must be had to the cost of fuel or prime motor power, and also to the cost of compressor, pipes, and machinery, as the saving in one is often secured by a sacrifice in the other.

Next to determining the size of pipe, the skilful engineer has need of further care in the proper position of reservoirs, branches, drains, and other attachments, as only by the exercise of good judgment in this can satisfactory working be secured. The fact that, on account of the diminished density of the atmosphere at high altitudes, air compressors do not give the same results as at sea level, should also be taken into consideration when a compressor is to be installed in a mountainous region.

**Friction of Air in Pipes.**—Air in its passage through pipes is subject to friction in the same manner as water or any other fluid; therefore, the pressure at the compressor must be greater than at the point of consumption, in order to overcome this resistance. The power that is needed to produce the extra

pressure representing the friction of the pipe is lost, as there can be no useful return for it. The friction is affected by very many circumstances; it is increased in direct proportion to the length of the pipe and also in the square of the velocity of the flow of air. The pressure of the air does not affect it.

The losses by friction may be quite serious if the piping system is poorly designed, and, on the other hand, extravagant expenditure in pipe may result from a timid overrating of the evils of friction. A thorough knowledge of the laws governing the whole matter, as well as a ripe experience, is necessary to secure true economy and mechanical success. The loss of power in pipe friction is not always the most serious result. When a number of machines are in use in a mine, and the pipes are so small as to cause considerable loss of pressure by friction, there will be sudden and violent fluctuations in pressure whenever a machine is started or stopped. Breakages will be common occurrences, as the changes are too quick to be entirely guarded against by the attendant; perfectly even pressure at the compressor is no safeguard against this class of accidents. The trouble arises in the pipe, and the remedy must be applied there. A system of reservoirs and governing valves will regulate these matters and allow successful work to be done with pipes that would otherwise be entirely inadmissible.

The ordinary formulas for calculating the volume of air transmitted through a pipe do not take into account the increase of volume due to reduction of pressure, i. e., loss of head. To transmit a given volume of air at a uniform velocity and loss of pressure, it is necessary to construct the pipe with a gradually increasing area. This, of course, is impracticable, and in a pipe of uniform section both volume and velocity must increase as the pressure is reduced by friction. The loss of head in properly proportioned pipes is so small, however, that in practice the increase in volume is usually neglected. The table on page 482 gives the loss of pressure by flow of air in pipes calculated for pipes 1,000 ft. long; for other lengths, the loss varies directly as the length.

The resistance is not varied by the pressure, only so far as changes in pressure vary the velocity. It increases about as the square of the velocity, and directly as the length. Elbows, short turns, and leaks in pipes all tend to reduce the pressure in addition to the losses given in the table. An elbow with a radius of one-half the diameter of the pipe is as short as can be made.

## LOSS BY FRICTION IN ELBOWS

| Radius of Elbow | Equivalent Length of Straight Pipe |
|---|---|
| *Diameters* | *Diameters* |
| 5 | 7.85 |
| 3 | 8.24 |
| 2 | 9.03 |
| $1\frac{1}{2}$ | 10.36 |
| $1\frac{1}{4}$ | 12.72 |
| 1 | 17.51 |
| $\frac{3}{4}$ | 35.09 |
| $\frac{1}{2}$ | 121.20 |

# DESIGN, OPERATION, AND INSTALLATION OF AIR COMPRESSORS

With regard to the design, installation, and operation of air compressors, the following suggestions made by Mr. Alex. M. Gow, Mechanical Engineer, Oliver Iron Mining Co., and slightly enlarged, will be of interest.

**Design for Avoiding Explosions.**—Clearance space should be reduced to a minimum. Ingoing air should traverse as small a surface of hot metal as possible. Discharge valves and passageways should contain no pockets or recesses for the accumulation of oil. Cylinders and heads should be water-jacketed; in some cases piston water-cooling may be resorted to. Stage compression, with adequate intercooling should be employed wherever final pressure and first cost of installation will warrant. Discharge valves must be easy of access for cleaning and examination. There must be no excuse for dirty or leaky valves.

**Installation of Compressor.**—Air should be drawn from the coolest and cleanest place possible, and never from the engine room. Engine-room air is never cool nor clean and an open intake is a constant invitation to squirt oil in from a can. Around collieries, it is well to consider the washing of the air. Coal dust drawn in with the air, mixes with the oil and forms a substance that,

on heating, cakes and may take fire. The discharge pipe should be of ample size and have as few bends as possible. A thermometer, preferably recording, should be placed on the discharge pipe. Provision for aftercooling should be made, a water spray will answer, to be used when the thermometer indicates the necessity. The receiver should be provided with a manhole for cleaning, and a drain easy of access and ample in size. Automatic sight-feed lubricators should be depended on for regular lubrication, but in addition an oil pump may be installed for the introduction of soap and water in case of necessity.

**Operation of Compressors.**—High flash-test cylinder oil of the best obtainable grade should be used for regular lubrication of the air cylinders. Mr. L. A. Christian advises that the flash point be 625° F., and that the oil should be comparatively free from unnecessary volatile carbon compounds. Volatile hydrocarbons tend to reduce the flash point, and, mixing with the dust from the air, form combustible deposits in the receiver and outlet passages. Further, oil of low-flash test, on reaching the interior of the heated air cylinder will be vaporized and will pass out with the air into the receiver without affording any lubrication to the wearing surfaces. If the oil is too dense or is compounded with animal or vegetable oils, as is the case with many steam-cylinder oils, it will have a tendency to adhere to the discharge valves and passages, and, being subjected to the dry heat of the compressed air, will gradually change to a hard, brittle crust, which in time will completely choke up the air passages or will prevent the valves seating. The amount of oil to be fed into the air cylinder should be, if the machine makes less than 120 rev. per min., about 1 drop every 3 min. Kerosene should never be used to cut or eat away deposits of carbon, as is sometimes done, as its flash point is about 120° F. If the cylinders or air passages need cleaning, soapsuds made of 1 part of soft soap and 15 parts of pure water should be fed into the cylinder and the machine worked with a liberal solution instead of oil for a few hours or a day; then the blow-off valve of the receiver should be opened and the accumulation of oil and water drained off. After this treatment and before the machine is shut down, oil should be fed into the cylinder for an hour or so, in order that the valves and the parts connected with the cylinder may be coated with oil and thus prevent rust.

Discharge valves must be kept tight; to this end the use of the steam engine indicator is advised. The cards may not tell much about the conditions of the valves, but one of the greatest values of the indicator is the moral effect upon the engineer. The valves should be cleaned from dust and oil and frequently examined.

Accumulations of water and oil must be blown from the receiver and an internal examination made at stated intervals.

The thermometer on the discharge pipe should be watched like the steam gauge. Before it reaches 400° F., the after cooling spray should be put on, and all the water-supply pipes and the discharge valves examined.

The engineer in charge should be thoroughly instructed as to the possibility of an explosion, the dangers attendant upon the use of any but the prescribed oil, and the effect of leaky discharge valves. He should be instructed in the use of the steam-engine indicator and required to submit cards at stated intervals. He should record in the engine-room log the daily conditions of the machines under his charge. He should be given a wholesome respect for an air compressor, with imperative instructions to keep it clean, inside as well as out.

# ELECTRICITY

## PRACTICAL UNITS

In electric work, it is necessary to have units in terms of which to express the different quantities entering into calculations. The unit quantity of electricity flowing through a circuit is called a coulomb. A *coulomb* is the quantity of electricity that will deposit from a solution of silver nitrate through which it flows .001118 gram of silver.

**Strength of Current.**—The strength of current flowing in a wire may be measured in several ways. If a compass needle is held under or over a wire it will be deflected and will tend to stand at right angles to the wire. The stronger the current, the greater is the deflection of the needle. If the wire carrying the current is cut and the end dipped into a solution of silver nitrate,

silver will be deposited on the end of the wire toward which the current is flowing, and the amount of silver deposited in a given time will be directly proportional to the average strength of current flowing during that time. When the current flowing in a wire is spoken of, the strength of the current is meant.

The unit used to express the strength of a current is called the *ampere*. If a current of 1 amp. be sent through a bath of silver nitrate, .001118 g. per sec. of silver will be deposited. The expression of the flow of current through a wire as so many amperes is analogous to the expression of the flow of water through a pipe as so many gallons per second. If 1 amp. flows through a circuit for 1 sec., the quantity of electricity that has passed through the circuit during the 1 sec. is 1 coulomb; that is, 1 coulomb is equal to 1 amp. for 1 sec.

**Electromotive Force.**—In order that a current may flow through a wire, there must be an electric pressure of some kind to cause the flow. In hydraulics, there must always be a head or pressure before water can be made to flow through a pipe. It is also evident that there may be a pressure or head without there being any flow of water, because the opening in the pipe might be closed; the pressure will, however, exist, and, as soon as the valve closing the pipe is opened, the current will flow. In the same way, an electric pressure or electromotive force (often written E. M. F.) may exist in a circuit, but no current can flow until the circuit is closed or until the wire is connected so that there will be a path for the current.

The practical unit of electromotive force is the *volt*. It is the unit of electric pressure, and fulfils somewhat the same purpose as head of water and steam pressure in hydraulic and steam engineering. The electromotive force furnished by an ordinary cell of a battery usually varies from .7 to 2 volts. A Daniell cell gives an electromotive force of 1.072 volts. A pressure of 500 volts is generally used for street-railway work, and, for incandescent lighting, 110 volts is common.

**Resistance.**—All conductors offer more or less resistance to the flow of a current of electricity, just as water encounters friction in passing through a pipe. The amount of this resistance depends on the length of the wire, the diameter of the wire, and the material of which the wire is composed. The resistance of all metals also increases with the temperature.

The practical unit of resistance is the *ohm*. A conductor has a resistance of 1 ohm when the pressure required to set up 1 amp. through it is 1 volt. In other words, the *drop*, or fall, in pressure through a resistance of 1 ohm, when a current of 1 ampere is flowing, is 1 volt. 1,000 ft. of copper wire .1 in. in diameter has a resistance of nearly 1 ohm at ordinary temperatures.

**Ohm's Law.**—The law governing the flow of current in an electric circuit was first stated by Dr. G. S. Ohm, and is known as *Ohm's law*. It may be briefly stated as follows: *The strength of the current in any circuit is equal to the electromotive force divided by the resistance of the circuit.*

Let $E$ = electromotive force, in volts;
$R$ = resistance, in ohms;
$I$ = current, in amperes.

Then, $I = \dfrac{E}{R}$ $R = \dfrac{E}{I}$ $E = IR$

EXAMPLE 1.—A dynamo $D$ generating 110 volts, is connected to a coil of wire $C$ that has a resistance of 20 ohms; what current will flow, supposing the resistance of the rest of the circuit to be negligible?

SOLUTION.—As $E = 110$ volts and $R = 20$ ohms, by Ohm's law $I = 110 \div 20 = 5.5$ amp.

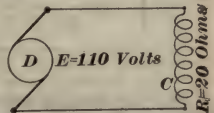
EXAMPLE 2.—If the resistance of the coil $C$ is 6 ohms, what electromotive force must the dynamo generate in order to set up a current of 15 amp. through it?

SOLUTION.—In this case the third formula will be used; that is, $E = 15 \times 6 = 90$ volts.

In case the current and electromotive force are known, the resistance of the circuit may be calculated by using the second formula.

EXAMPLE 3.—If the current in the previous examples were 8 amp. and the electromotive force of the dynamo 110 volts, what is the resistance of the circuit?

SOLUTION.— $R = 110 \div 8 = 13.75$ ohms.

**Electric Power.**—The electric power expended in any circuit is found by multiplying the current flowing in the circuit by the pressure required to force


the current through the circuit. In other words, $W = EI$, where $W$ is the power expended, $E$ is the electromotive force and $I$ is the current. When $E$ is expressed in volts and $I$ in amperes, then $W$ is expressed in watts. The *watt* is the unit of electric power, and is equal to the power developed when 1 amp. flows under a pressure of 1 volt. The watt is equal to $\frac{1}{746}$ H. P.

Let
$$E = \text{electromotive force, in volts;}$$
$$I = \text{current, in amperes;}$$
$$R = \text{resistance, in ohms;}$$
$$W = \text{power, in watts;}$$
$$\text{H. P.} = \text{horsepower.}$$

Then,
$$W = EI = I^2 R = \frac{E^2}{R}$$

The energy used in forcing a current through the wire reappears in the form of heat; the heating effect of a current flowing in a conductor being proportional to the square of the current. Furthermore,

$$\text{H. P.} = \frac{EI}{746} = \frac{W}{746}$$

This relation is very useful for calculating power in terms of electric units. The watt is too small a unit for convenient use in many cases, so that the *kilowatt*, or 1,000 watts, is frequently used. This is sometimes abbreviated to K. W.

The unit of work is the *watt-hour*, which is the total work done when 1 watt is expended for 1 hr. For example, if a current of 1 amp. flows for 1 hr. through a resistance of 1 ohm, the total amount of work done is 1 watt-hour. A kilowatt-hour is the total work done when 1 K. W. is expended for 1 hr. It is about equivalent to $1\frac{1}{3}$ H. P. for 1 hr. The work done when 1 watt is expended for 1 sec. is called the *joule;* or 1 joule is expended in a circuit when 1 volt causes 1 amp. to pass through the circuit for 1 sec.

## ELECTRICAL EXPRESSIONS AND THEIR EQUIVALENTS

(*Arranged for Convenient Reference by C. W. Hunt*)

| 1 Watt | Rate of doing work | | 1 Watt-Hour | Quantity of work | |

| | .746 | K. W. | | Force of 1 lb. at a radius of 1 ft. | |

## CIRCUITS

The path through which a current flows is generally spoken of as an *electric circuit;* this path may be made up of a number of different parts. For example, the line wires may constitute part of the circuit, and the remainder may be composed of lamps, motors, resistances, etc. In practice, the two kinds of circuits most commonly met with are those in which the different parts of the circuit are connected in series and those in which they are connected in multiple or parallel.

**Series Circuits.**—In a series circuit, all the component parts are connected in tandem, so that the current flowing through one part also flows through the other parts; view (*a*) represents such a circuit made up of a different number

of parts. The current leaves the dynamo $D$ at the $+$ side and flows through the arc lamps $a$, thence through the incandescent lamps $l$, thence through the motor $m$ and resistance $r$, back to the dynamo, thus making a complete circuit. All these parts are here connected in series, so that the current flowing through each of the parts must be the same unless leakage takes place across from one side of the circuit to the other, and this is not appreciable if the lines are properly insulated. The pressure furnished by the dynamo must evidently be the sum of the pressures required to force the current through the different parts.

The most common use of this system is in connection with arc lamps, which are usually connected in series, as shown in (b). The objections to

(a)

(b)

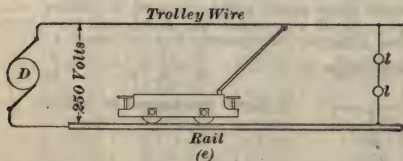
(c)

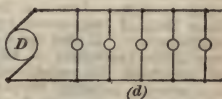
(d)

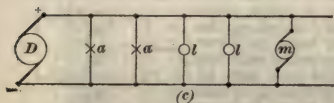
*Trolley Wire*

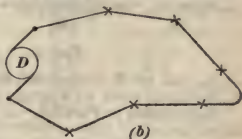
250 Volts

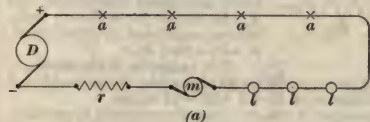
*Rail*

(e)










this system of distribution for general work are that the breaking of the circuit at any point cuts off the current from all parts of the circuit; also, the pressure generated by the dynamo must be very high if many pieces of apparatus are connected in series. In such a system, the dynamo is provided with an automatic regulator that increases or decreases the voltage of the machine, so that the current in the circuit is kept constant, no matter how many lamps or other devices are in operation. For this reason, such systems are often spoken of as constant-current circuits.

**Parallel Circuits.**—In a parallel circuit, the different pieces of apparatus are connected side by side, or in parallel, across the main wires from the dynamo as shown in (c). In this case, the dynamo $D$ supplies current through the mains to the arc lamps $a$, incandescent lamps $l$, and motor $m$. This system is more widely used, as the breaking of the circuit through any one piece of apparatus will not prevent the current from flowing through the other parts. Incandescent lamps are connected in this way almost exclusively. The lamps are connected directly across the mains, as shown in (d). Street cars and mining locomotives are operated in the same way, the trolley wire constituting one main and the track the other, as shown in (e). By adopting this system, any car can move independently of the others, and the current in each device may be turned off and on at will without affecting devices in other parallel circuits. In all these systems of parallel distribution, the pressure generated by the dynamo is maintained as constant as practicable, no matter what current the dynamo may be delivering. For example, in the lamp system, view (d), the dynamo will maintain a constant electromotive force of 110 volts. Each lamp has a fixed resistance, and will take a certain current ($110 \div R$ amperes) when connected across the mains. As the lamps are turned on, the current delivered by the dynamo increases, the pressure remaining constant. In street-railway work, the pressure between trolley and track is kept in the neighborhood of 500 volts, the current varying with the number of cars in operation. In mine-haulage plants, the pressure is usually 250 or 500 volts, the former being generally preferred as being less dangerous. Lamps may also be connected in series multiple, as shown in (e). Here the two 125-volt lamps $l$

are connected in series across the 250-volt circuit. Such an arrangement is frequently used in mines when lamps are operated from the haulage circuit.

Such circuits as those just described are called *constant-potential* or *constant-pressure* circuits, to distinguish them from the *constant-current* circuit mentioned previously.

## RESISTANCES IN SERIES AND MULTIPLE

**Resistance in Lines.**—If two or more resistances are connected in series, as in Fig. 1, their total combined resistance is equal to the sum of their separate resistances. If $R$ equals total combined resistance, and $R_1$, $R_2$, $R_3$ are the separate resistances connected in series, then,

$R_1$ $R_2$ $R_3$

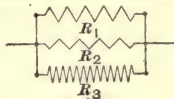
Fig. 1

$$R = R_1 + R_2 + R_3.$$
For example, if the separate resistances are $R_1 = 10$ ohms, $R_2 = 1$ ohm, and $R_3 = 30$ ohms, the three combined will be equivalent to a single resistance of $10 + 1 + 30 = 41$ ohms.

**Resistances in Parallel.**—If a number of resistances are connected in parallel, the reciprocal of their combined resistance is equal to the sum of the reciprocals of the separate resistances. In Fig. 2, three resistances are shown connected in parallel; therefore, the total resistance of such a combination must be lower than that of the lowest resistance entering into the combination. If the resistances in this case were all equal, the resistance of the three combined would be one-third the resistance of one of them, because a current passing through the three combined

$R_1$
$R_2$
$R_3$

Fig. 2

could split up equally between three equal paths, instead of having only one path to pass through. If $R$ represents the combined resistance, and $R_1$, $R_2$, $R_3$, and $R_4$, the separate resistances, the following relation is true for any number of resistances in parallel: $\dfrac{1}{R} = \dfrac{1}{R_1} + \dfrac{1}{R_2} + \dfrac{1}{R_3} + \dfrac{1}{R_4} +$ etc.


from which $R = \dfrac{1}{\dfrac{1}{R_1} + \dfrac{1}{R_2} + \dfrac{1}{R_3} + \dfrac{1}{R_4} + \text{etc.}}$. If three resistances in parallel are

equal, $\dfrac{1}{R} = \dfrac{3}{R_1}$, or $R = \dfrac{R_1}{3}$.

EXAMPLE.—Three resistances of 3, 10, and 5 ohms are connected in parallel; what is their combined resistance?

SOLUTION.— $\dfrac{1}{R} = \dfrac{1}{3} + \dfrac{1}{10} + \dfrac{1}{5}$ or, $R = \dfrac{1}{\frac{10}{30} + \frac{3}{30} + \frac{6}{30}} = \dfrac{30}{19} = 1.58$ ohms.

If resistances in parallel are all equal, the current will divide equally through them; if not equal, the current in each path will be inversely proportional to the resistance of the path. In any case, the current through any path is equal to the difference of potential across the path divided by its resistance.

$A$

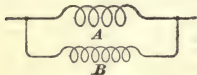
$B$


Fig. 3

**Shunt.**—When one circuit $B$, Fig. 3, is connected across another $A$, so as to form, as it were, a by-pass, or side track, for the current, such a circuit is called a *shunt*, or it is said to be in shunt with the other circuit

## ELECTRIC WIRING (CONDUCTORS)

**Materials.**—Practically all conductors used in electric lighting or power work are of copper, this metal being used on account of its low resistance. Iron wire is used to some extent for conductors in telegraph lines, and steel is largely used as the return conductor in electric-railway or haulage plants where the current is led back to the power station through the rails. The resistance of iron or steel varies from six to seven times that of copper, depending on the quality of the metal. Aluminum is coming into use in electric transmission. It is so much lighter than copper that it is able to compete with it as a conductor, even though its cost per pound is higher and its conductivity only about 60% that of copper.

Most of the conductors used are in the form of copper wire of circular cross-section. Conductors of large cross-section are made up of a number of strands of smaller wire twisted together. For electrolytic plants, copper-refining plants, etc., copper bars of rectangular cross-section are frequently used. On account of the method used in supporting the larger sizes, large trolley wires are not always of circular cross-section.

**Wire Gauge.**—The gauge most generally used in America to designate the different sizes of copper wire is the American, or Brown & Sharpe (B. & S.). The sizes as given by this gauge range from No. 0000, the largest, .460 in. diameter, to No. 40, the finest, .003 in. diameter. Wire drawn to the sizes given by this gauge is always more readily obtained than sizes according to other gauges; hence, when selecting wire for any purpose it is always desirable, if possible, to give the size required as a wire of the B. & S. gauge. A wire can usually be selected from this gauge, which will be very nearly that required for any specified case.

The diameter of round wires is usually given in the tables in decimals of an inch and the so-called area of cross-section is given in terms of a unit called a circular mil. This is done simply for convenience, as it makes calculations involving the cross-section much simpler than if the square inch was used as the unit area. A *mil* is $\frac{1}{1000}$ in., or .001 in. A *circular mil* is the square of the diameter of a wire expressed in mils. A wire having a diameter of 1 in. has a sectional area of $.7854 \times 1^2 = .7854$ sq. in., and is said to have a sectional area of $1,000^2 = 1,000,000$ circular mils. Hence, *the area of cross-section of a wire in circular mils is equal to the square of its diameter expressed in mils.* CM is frequently used as an abbreviation for circular mils.

EXAMPLE.—A wire has a diameter of .101 in.; what is its area in circular mils?
SOLUTION.— .101 in. = 101 mils. Hence, $(101)^2 = 10,201$ CM.

### CARRYING CAPACITY OF COPPER CABLES

### COMPARISON OF PROPERTIES OF ALUMINUM AND COPPER

| | Aluminum | Copper |
|---|---|---|
| Conductivity, for equal sizes........... | .54 to .63 | 1 |
| Weight, for equal sizes................ | .33 | 1 |
| Weight, for equal length and resistance.. | .48 | 1 |
| Price of bare wire, per pound, aluminum, 29 c.; copper, 16 c................ | 1.81 | 1 |
| Price, equal length and resistance, bare line wire........................ | .868 | 1 |
| Temperature coefficient, per degree F.... | .002138 | .002155 |
| Resistance of mil-foot, at 20° C......... | 18.73 | 10.5 |
| Specific gravity....................... | 2.5 to 2.68 | 8.89 to 8.93 |
| Breaking strength, equal sizes.......... | 1 | 1 |

The table on page 489 gives the dimensions, weight, and resistance of annealed copper wire. The weights given are, of course, for bare wire. The first column gives the B. & S. gauge number, the second the diameter in mils. The diameter in inches will be the number given in this column, divided by 1,000. The third column gives the area in circular mils, the numbers in this column being equal to the squares of those in the second column. The safe carrying capacity is also given. In case a conductor larger than that given in the table is required, stranded cables are used; these are made in various sizes. The first table on page 490 gives some of the more common sizes of stranded copper cables, with their allowable current capacity, while a comparison of the properties of aluminum and copper is given in the second table on page 490.

**Estimation of Resistance.**—The resistance of any conductor is directly proportional to its length, and inversely proportional to its area of cross-section, or $R = K \frac{L}{A}$, where $K$ is a constant. If $L$ is expressed in feet and $A$ is expressed in circular mils, the constant $K$ must be the resistance of 1 ft. of the wire in

### BREAKING STRENGTH OF COPPER AND ALUMINUM WIRES AND CABLES

| Wire Number B. & S. Gauge | Area Circular Mils | Breaking Strain, Pounds | | | |
|---|---|---|---|---|---|
| | | Copper, Solid | | Aluminum | |

question of 1 circular mil cross-section. The resistance of 1 mil-ft. of copper wire at 75° F. is about 10.8 ohms. Hence, for copper wire, $R = \frac{10.8L}{d^2}$, in which $d$ is the diameter in mils. This formula is easily remembered, and is very convenient for estimating the resistance of any length of wire of given diameter when a wire table is not at hand, or when the diameter of the given wire does not correspond to anything given in the table.

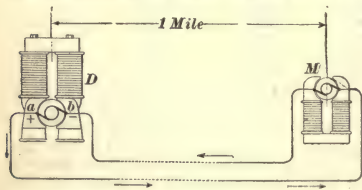
EXAMPLE.—Find the resistance of 1 mi. of copper wire .20 in. in diameter.
SOLUTION.—1 mi. = 5,280 ft.; .20 in. = 200 mils, or 40,000 C. M.; hence,
$$R = \frac{10.8 \times L}{d^2} = \frac{10.8 \times 5,280}{40,000} = 1.42 \text{ ohms}$$

The breaking strengths of copper and aluminum wires and cables are given in the preceding table. The ultimate strength of annealed copper is taken as 34,000 lb. per sq. in.; of hard-drawn copper, as 60,000 lb. per sq. in., except that for Nos. 000 and 00 it is taken at 50,000 lb., for No. 0 at 55,000 lb., and for No. 1 as 57,000 lb. The ultimate strength of aluminum is taken as 26,000 lb. per sq. in. The table gives the actual breaking strains to which a suitable factor of safety must be applied to give a safe working load.

# CALCULATION OF WIRES FOR ELECTRIC TRANSMISSION

**Direct-Current Circuits.**—No matter how large a wire may be, some energy must always be expended in forcing a current through it, because no conductor can be entirely devoid of resistance. It is true that the loss may be made as small as desired by using a very large conductor, but in practice this will not pay, because the interest on the cost of the copper will more than counterbalance the gain in the efficiency of transmission. In starting out, then, to estimate the size of wire to transmit a given amount of power over a given distance, one of the first things to be decided is the amount of power that may be allowed for loss in the line, because the greater the power lost the higher may be the line resistance, and hence the smaller the wire. The pressure required to force a current $I$ through a wire of a resistance $R$ is $I \times R$. This pressure is generally spoken of as the *drop*, for the reason that the pressure necessary to set up the current through the line is lost, and, consequently, the pressure falls off or drops from the dynamo to the receiving end of the line. In all cases, the pressure at the end of the line, or point where the power is delivered, is equal to the pressure at the dynamo less the drop in the line, and, conversely, the pressure that must be maintained by the dynamo in order to obtain a given pressure at the end of the line will be equal to the pressure at the receiving end plus the drop in the line.

This is shown in the accompanying illustration, where a dynamo $D$ supplies current to a motor $M$ situated 1 mi. distant. In order that the motor may operate properly, the pressure at its terminals must be kept constant at, say 500 volts; therefore, the pressure between $a$ and $b$ (the dynamo terminals) must be more than 500 volts by the drop or pressure necessary to force the current through the line. If the motor is taking very little current, that is, if it is running on a very light load, the current will be small, and hence the drop in the line will be small. In order, then, that the pressure at the motor may remain constant, or nearly so, the pressure at the dynamo must automatically increase as the load increases and the line must be designed with regard to the maximum current it has to carry. It will be supposed that the motor takes 50 amp. at full load and that the line wire has a resistance of .2 ohm per mi. The current has to pass through 2 mi. of wire (because it has to flow out through 1 mi. and back through 1 mi.), and hence encounters a resistance of .4 ohm. The drop in the line will then be $.4 \times 50 = 20$ volts, and in order to obtain a pressure of 500 volts at the motor, the pressure at the dynamo will have to be 520 volts. The loss of power in the line would be current $\times$ drop $= 50 \times 20 = 1,000$ watts, or about $1\frac{1}{3}$ H. P. The drop in an electric-transmission line is analogous to the loss in pressure due to the friction encountered by water flowing through a pipe line.



If, in the illustration just given, the wire had a resistance of .1 ohm per mi., the loss in the line would be halved, but the weight of copper required would have to be double the cross-section. The question as to whether it would pay better to invest more money in the line or to put up with the larger loss is something that must be determined in each case by the relative cost of power and copper.

In many cases, the loss allowed in the line is about 10% of the power to be delivered, though sometimes the loss may be allowed to run as high as 15% or 25%. This applies only to transmission lines. For local electric-light or power-distributing systems, the amount of drop allowed is usually about 2% for the former and 5% for the latter.

The problem of calculating line wires usually presents itself in the following form: Given, a certain amount of power to transmit over a known distance with a certain allowable loss, to determine the cross-section of the wire required.

Let   $P$ = power to be delivered, expressed in watts; $P$ will be equal to horsepower delivered at end of line multiplied by 746;

% = allowable percentage of loss in line, that is, percentage of power
delivered that may be lost in transmission;

$E$ = voltage at end of line where power is delivered;

$I$ = current at full load;

$L$ = length of wire through which current flows.

The cross-section of the copper conductor will then be given by the formula:

$$A = d^2 = \frac{10.8 \times L \times I \times 100}{E \times \%}$$

The circular mils will be $d^2$, and the corresponding size of wire may be found by consulting the wire table. It should be noticed, particularly, that in this formula, $L$ is the average length of conductor through which the current $I$ flows. The application of distance of transmission in the formula is shown in the following example:

EXAMPLE.—A mine pump, driven by an electric motor, is situated 2 mi. from the power station. The electric input of the motor at full load is 50 H. P., and the voltage at its terminals is to be 500. Estimate the size of line wire necessary to supply the motor, the allowable loss in the line being 15% of the power delivered.

SOLUTION.—The actual length of line through which the current will flow will be 4 mi., because the current has to flow out to the motor and back again. Then

$$I = \frac{watts}{E} = \frac{50 \times 746}{500} = 74.6 \text{ amp.}$$

Applying the formula,

$$A = d^2 = \frac{10.8 \times 2 \times 2 \times 5,280 \times 74.6 \times 100}{500 \times 15} = 226,880 \text{ C. M., nearly}$$

By consulting the wire table it is found that this calls for a wire a little larger than No. 0000, which has a cross-section of 211,600 C. M.; No. 0000 wire would probably be used in this case, as it is near enough to the calculated size for all practical purposes. In case the calculated size comes out larger than any size given in the table, a number of wires may be used in multiple to make up the required cross-section, or, what is better, a stranded cable may be used. These heavy stranded cables may now be obtained in different sizes, up to 2,000,000 C. M. cross-section.

If it were allowable to waste twice as much power in the line, or what is equivalent to having a line drop of 150 volts instead of 75 volts, the cross-section of wire required would be one-half of that just found. Such a large amount of loss would, however, be objectionable unless power was very cheap. A large drop in the line is in any case objectionable, because the voltage at the receiving end of the circuit will fall off greatly unless the voltage at the generating station is raised as the load comes on in order to compensate for the line drop. Most of the uses to which electricity is put, in mines or other places, require that the pressure at the point where the power is utilized shall be kept approximately constant. For example, in the case of incandescent lights, the lamps will fall off greatly in brightness if the pressure decreases even by a comparatively slight amount. Also, if motors are being operated, the speed will vary considerably if the pressure is not kept constant, and it may be stated, in general, that a large line loss tends to poor regulation at the end of the circuit where power is delivered.

From these considerations, it is evident that the size of wire to be used under given conditions is determined by the allowable amount of drop. In some cases, however, especially if the current is to be used near at hand, the size of wire so determined might not be large enough to carry the current without overheating. Of course, in such cases, the safe carrying capacity of the wire determines the size to be used, and the drop will be correspondingly less. The amount of current that a given wire can carry without overheating depends very largely on the location of the wire. For example, a wire strung in the open air will carry a greater current, with a given temperature rise, than the same wire when boxed up in a molding or conduit.

In order to keep down the size of wire required to transmit a given amount of power over a given distance, with a certain allowable loss, the current must be kept as small as possible. Now, for a given amount of power, the current can only be made small by increasing the pressure, because the number of watts, or power delivered, is equal to the product of the current and the pressure. As a matter of fact, if the pressure in any given case is doubled, the amount of copper required will be only one-fourth as great; in other words, for a given

amount of power transmitted, the weight of copper required decreases as the square of the voltage. It is at once seen, then, that if any considerable amount of power is to be transmitted over long distances, a high line pressure must be used or else the cost of copper becomes prohibitive. The use of high pressures in power transmission will be taken up in connection with alternating currents.

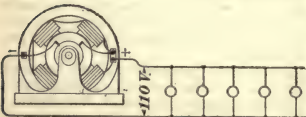
**Insulated Wires.**—For most overhead line work using modern voltages, weather-proof insulated wire is used. This wire is covered with two or three braids of cotton, and treated with insulating compound. For inside work, and in places where a better quality of insulation is required, rubber-covered wires are used. The accompanying table gives the approximate weight of weather-proof line wire. The cost of the wire per pound varies considerably, owing to variations in the price of copper.

### WEATHER-PROOF LINE WIRE (ROEBLING'S)

| Number B. & S. Gauge | Double Braid | | | Triple Braid | | |
| | Outside Diameter 32ds In. | Weight, in Pounds | | Outside Diameter 32ds In. | Weight, in Pounds | |
| | | Per 1,000 Ft. | Per Mile | | Per 1,000 Ft. | Per Mile |
| 0000 | 20 | 716 | 3,781 | 24 | 775 | 4,092 |
| 000 | 18 | 575 | 3,036 | 22 | 630 | 3,326 |
| 00 | 17 | 465 | 2,455 | 18 | 490 | 2,587 |
| 0 | 16 | 375 | 1,980 | 17 | 400 | 2,112 |
| 1 | 15 | 285 | 1,505 | 16 | 306 | 1,616 |
| 2 | 14 | 245 | 1,294 | 15 | 268 | 1,415 |
| 3 | 13 | 190 | 1,003 | 14 | 210 | 1,109 |
| 4 | 11 | 152 | 803 | 12 | 164 | 866 |
| 5 | 10 | 120 | 634 | 11 | 145 | 766 |
| 6 | 9 | 98 | 518 | 10 | 112 | 591 |
| 8 | 8 | 66 | 349 | 9 | 78 | 412 |
| 10 | 7 | 45 | 238 | 8 | 55 | 290 |
| 12 | 6 | 30 | 158 | 7 | 35 | 185 |
| 14 | 5 | 20 | 106 | 6 | 26 | 137 |
| 16 | 4 | 14 | 74 | 5 | 20 | 106 |
| 18 | 3 | 10 | 53 | 4 | 16 | 85 |

For high-tension lines, it is customary to use bare wires and insulate them thoroughly on special porcelain insulators. The ordinary weather-proof wire insulation is of little or no use as a protection when these high pressures are used, and it only makes the line more dangerous because of the false appearance of security that it gives. In many cases, it is also better to use bare feeders for mine-haulage plants, because the ordinary insulation soon becomes defective in a mine, and a wire in this condition is really more dangerous than a bare wire, because the latter is known to be dangerous and will be left alone.

## CURRENT ESTIMATES

FIG. 1


**Incandescent Lamps.**— Before calculating the size of wire required for any given case, it is necessary to know the current, and the method of getting at this will depend on what the current is to be used for. Incandescent lamps are usually operated on 110-volt circuits, as shown in Fig. 1, or on the three-wire system, as shown in Fig. 2. In the three-wire system, two 110-volt dynamos are connected in series so that the voltage across the outside wires is 220. The neutral wire *a* connects at

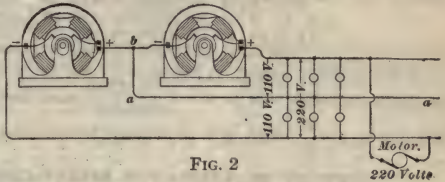
the point $b$ where the machines are connected together. The wire $a$ merely serves to carry the difference in the currents on the two sides of the system, in case more lamps should be burning on one side than on the other. The outside wires for such a system are calculated as if the lights were operated two in series across 220 volts. The middle wire is usually made equal in size to the outer wires. An ordinary 16-c. p. incandescent carbon-filament lamp requires about 55 watts for its operation; a 32-c. p. lamp requires about 110 watts. Tungsten lamps are designated by the watts required rather than by the candlepower light they give. Thus, a 25-watt tungsten lamp gives about 20 c. p. Hence, in the case of ordinary parallel distribution, as shown in Fig. 1, the dynamo will deliver about $\frac{1}{2}$ amp. for each 16-c. p. carbon lamp operated, and 1 amp. for each 32-c. p. carbon lamp. In the case of the three-wire system, each pair of 16-c. p. carbon lamps will take $\frac{1}{2}$ amp., and the total number of amperes in the outside wires will be one-fourth the number of lamps operated.


FIG. 2

EXAMPLE 1.—A certain part of a mine is to be illuminated by fifty 16-c. p. carbon lamps and ten 32-c. p. carbon lamps. This portion of the mine is 1,000 ft. from the dynamo room, and the allowable drop in pressure is 5%. The lamps are to be run on a 110-volt system. Find the size of wire required.

SOLUTION.—Fifty 16-c. p. carbon lamps require .... 25 amperes
Ten 32-c. p. carbon lamps require ..... 10 amperes

Total current..................... 35 amperes

$$\frac{10.8 \times 1,000 \times 2 \times 35 \times 100}{110 \times 5} = 137,454 \text{ C. M.,}$$

or about a No. 00 B. & S. wire.

EXAMPLE 2.—Take the same case, but suppose the lights to be operated on the three-wire system.

SOLUTION.—There will then be twenty-five 16-c. p. carbon lamps and five 32-c. p. carbon lamps on each side of the circuit, and the total current in the outside wires will be 17.5 amp. The voltage between the outside wires will be 220, and

$$\frac{10.8 \times 1,000 \times 2 \times 17.5 \times 100}{220 \times 5} = 34,363 \text{ C. M.,}$$

or about a No. 5 B. & S. wire.

If the central wire is made also of this size, this system would require three-eighths the amount of copper called for by the plain 110-volt system. There is the disadvantage that two dynamos are needed.

NOTE.—The length to be used in the wiring formula is the average distance traversed by the current in the conductor. For example, if, as in Fig. 3 (a), the lamps were all grouped or bunched at the end of the line, the length used in the formula would be twice that from $G$ to $A$, because the whole current has to flow out to $A$ through one main and back through the other. In other words, the whole current here passes through the whole length of the line. In case the load is uniformly distributed all along the line, as shown in (b), the current decreases step by step from the dynamo to the end. In such a case, the length or distance to be used in the formula is one-half that used in the former case, or simply the distance from the dynamo to the end, instead of twice this distance.

**Arc Lamps.**—Arc lamps are frequently run on constant-potential circuits, and usually consume from 400 to 500 watts. There are so many types of these lamps that it is difficult to give any current estimates that will be generally applicable. Enclosed arc lamps usually take from 3 to 5 amp. when run on 110-volt circuits.

**Motors.**—Practically all the motors used in mining work are run on the constant-potential system, either at 250 or 500 volts. The efficiency of ordinary motors will vary from 65% to 94%, depending on the size. The efficiency is greater with the larger machines, and, for the ordinary run of motors, it will

probably lie between 80% and 90%. By efficiency is here meant the ratio of the useful output at the pulley or pinion of the motor to the total input. The following table gives the efficiency of motors of ordinary size:

*Approximate Motor Efficiency*

$\frac{3}{4}$ to $1\frac{1}{2}$ H. P., inclusive = 70–75% efficiency
3 to 5 H. P., inclusive = 75–80% efficiency
$7\frac{1}{2}$ to 10 H. P., inclusive = 80–85% efficiency
15 H. P. and upwards = 85–90% efficiency

If the required output, in horsepower, of a direct-current motor is known, the input, in watts, will be $W = \dfrac{\text{H. P.} \times 746}{\text{efficiency}}$, and the current required at full load will be $I = \dfrac{W}{E}$, where $E$ is the voltage between the mains at the motor.

### CURRENT REQUIRED FOR DIRECT-CURRENT MOTORS

| Horse-power of Motor | Effi-ciency* Per Cent. | Watts Input | Amperes | | | | |
|---|---|---|---|---|---|---|---|
| | | | 110 Volts | 220 Volts | 250 Volts | 500 Volts | 550 Volts |
| 1 | 65 | 1,148 | 10.4 | 5.2 | 4.58 | 2.29 | 2.08 |
| 2 | 65 | 2,295 | 20.8 | 10.4 | 9.16 | 4.58 | 4.16 |
| 2½ | 65 | 2,870 | 26.0 | 13.0 | 11.45 | 5.72 | 5.21 |
| 3½ | 75 | 3,481 | 31.6 | 15.8 | 13.90 | 6.90 | 6.32 |
| 5 | 75 | 4,973 | 45.1 | 22.6 | 19.90 | 9.95 | 9.04 |
| 7½ | 80 | 6,994 | 63.5 | 31.7 | 27.90 | 13.95 | 12.70 |
| 10 | 80 | 9,325 | 84.6 | 42.3 | 37.20 | 18.60 | 16.90 |
| 15 | 85 | 13,165 | 119.8 | 59.9 | 52.70 | 26.40 | 23.90 |
| 20 | 85 | 17,553 | 159.6 | 79.8 | 70.20 | 35.10 | 31.90 |
| 25 | 90 | 20,770 | 189.0 | 94.5 | 83.10 | 41.60 | 37.80 |
| 30 | 90 | 24,864 | 225.8 | 112.9 | 99.40 | 49.70 | 45.20 |
| 40 | 90 | 33,232 | 302.6 | 151.3 | 133.00 | 66.50 | 60.50 |
| 50 | 90 | 41,540 | 378.0 | 189.0 | 166.20 | 83.10 | 75.60 |
| 75 | 90 | 62,310 | 567.0 | 283.5 | 249.30 | 124.80 | 113.40 |
| 100 | 93 | 80,215 | 729.0 | 364.5 | 320.50 | 160.30 | 145.70 |
| 125 | 93 | 100,269 | 912.0 | 456.0 | 401.00 | 200.50 | 182.30 |
| 150 | 93 | 120,322 | 1,094.0 | 547.0 | 481.00 | 240.70 | 219.00 |
| 200 | 94 | 158,510 | 1,442.0 | 721.0 | 634.00 | 317.00 | 288.00 |

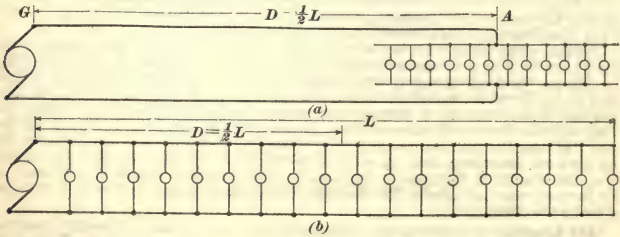

Fig. 3

**Conductors for Electric-Haulage Plants.**—In electric-haulage plants, the rails take the place of one of the conductors, so that, in calculating the size of feeders required, only the overhead conductors are taken into account. It

*Efficiencies are taken arbitrarily; a variation in these percentages will make proportionate changes in watts and amperes.

is a difficult matter to assign any definite value to the resistance of the track circuit, as it depends very largely on the quality of the rail bonding at the joints. If this bonding is well done, the resistance of the return circuit should be very low, because the cross-section of the rails is comparatively large. For calculating the supply feeders, the following approximate formula may be used:

$$\text{circular mils} = \frac{14 \times L \times I \times 100}{E \times \% \text{ drop}}$$

In this case, $L$ is the average length of feeder over which the power is to be transmitted. It will be noticed that the constant 10.8 appearing in the previous formulas has here been increased to 14. This has been done to allow, approximately, for the track resistance, but this constant might vary considerably depending on the quality of the rail bonding. If the load is all bunched at the end of the feeder, $L$ is the actual length of the feeder in feet. If the load is uniformly distributed, as it would be if a number of locomotives were continually moving along the line, the distance $L$ in the formula will be taken as one-half that used in the case where the load is bunched at the end. In other words, the whole current $I$ will only flow through an average of one-half the length of the line.

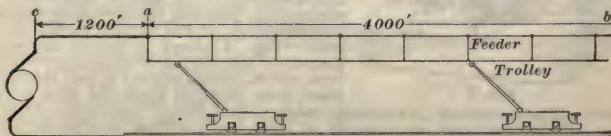

Fig. 4

EXAMPLE.—In Fig. 4, $ab$ represents a section of track 4,000 ft. long. From the dynamo $c$ to the beginning of the section, the distance is 1,200 ft. The trolley wire is No. 00 B. & S., and is fed from the feeder at regular intervals. Two mining locomotives are operated, each of which takes an average current of 75 amperes. The total allowable drop to the end of the line is 5% of the terminal voltage, which is 500 volts. Calculate the size of feeder required, assuming that the constant 14, in the formula, takes account of the resistance of the return circuit.

SOLUTION.—Since the locomotives are moving from place to place, the center of distribution for the load may be taken at the center of the 4,000 ft. The distance $L$ will then be $1,200 + 2,000 = 3,200$ ft. The total current will be 150 amperes; hence, we have

$$\text{circular mils} = \frac{14 \times 3,200 \times 150 \times 100}{500 \times 5} = 268,800.$$

This would require either a stranded cable or the use of two No. 00 wires in parallel from $c$ to $a$. From $a$ to $b$ we have the No. 00 trolley wire in parallel with the feeder; hence, the section of feeder $ab$ may be a single No. 00 wire. In many cases, the drop is allowed to run as high as 10%, because the loads are usually heavier, and the distances longer, than in the example given above.

## DYNAMOS AND MOTORS

### DIRECT-CURRENT DYNAMOS

A *dynamo*, or *generator*, is a machine for converting mechanical energy into electrical energy by moving conductors relatively to a magnetic field. An *electric motor* is a machine for converting electrical energy into mechanical energy by the relative motion between conductors carrying a current and a magnetic field. In the case of a dynamo a number of conductors are made to move across a magnetic field by means of a steam engine or other prime mover, and the result is that an electromotive force is set up in the conductors, and this electromotive force will set up a current if the circuit is closed.

In the case of a motor, a number of conductors are arranged so that they are free to move across a magnetic field, and a current is sent through these conductors from some source of electric current. The current flowing through these conductors reacts on the magnetic field and causes the conductors to move, thus converting the electrical energy delivered to the motor into mechanical

32

energy. As far as mechanical construction goes, dynamos and motors are almost identical, and the operation of the motor is about the reverse of that of the dynamo.

Dynamos and motors may be divided into two general classes: Dynamos and motors for direct current; dynamos and motors for alternating current.

FIG. 1

*Direct-current dynamos* are those that furnish a current that always flows in the same direction. This kind of dynamo is largely used for incandescent lighting, and also for the operation of street railways. A dynamo generates an electromotive force by the motion of conductors across a magnetic field; hence, there must be a magnet of some kind to set up a magnetic field, known as the *field magnet*, or simply as the *field;* and a series of conductors arranged so that they may be moved or revolved in the magnetic field, known as the *armature.* The field is supplied by means of a powerful electromagnet which is magnetized by the current in the field coils. Fig. 1 shows a typical six-pole magnet of this kind; *B* are the magnetizing coils, which, when a current is sent through them, form powerful magnetic poles at *N* and *S.* The framework *A* is usually made of cast iron or cast steel. These field magnets may have any number of poles, but machines of ordinary size are usually provided with from two to eight poles.

The armature usually consists of a number of turns of insulated copper wire, arranged around the periphery of a ring or drum built up of soft iron sheets. Fig. 2 shows the construction of a typical armature of the ring type. The winding is divided into a number of sections, and the terminals connected to the *commutator.*

This commutator consists of a number of copper bars, insulated from each other by means of mica, the bundle of bars being clamped firmly into place

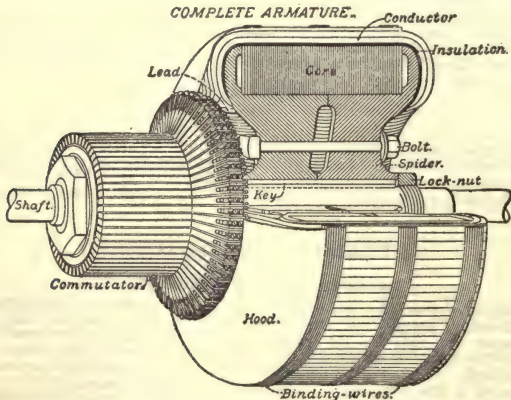
COMPLETE ARMATURE.


FIG. 2

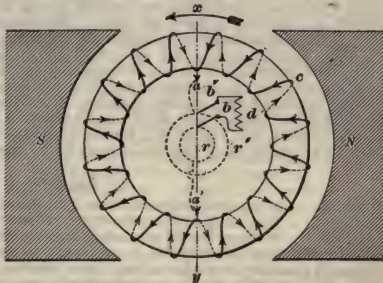
and turned up to form a true cylindrical surface. The sections in the commutator correspond with those in the armature, and the use and operation of the commutator will be described later. The winding on the ring is endless, that is, it consists of a number of coils or sections *c*, Fig. 3, the end of one section

being joined to the beginning of the next, thus forming an endless coil. The construction of such a ring armature would be as shown in Fig. 2.

Suppose that the ring shown in Fig. 3 with its endless winding is rotated between the poles of a two-pole field magnet. Magnetic lines will flow from the N pole of the field magnet across through the iron core of the armature and enter the S pole on the other side. As all the conductors on the right-hand face of the ring are moving upwards, they will have an electromotive force generated in them in one direction, while the conductors on the left side will have an electromotive force in the opposite direction, because all the conductors on this side are moving downwards, or in the opposite direction, to those on the other side. These two opposing electromotive forces may be said to start at $a'$ and to meet at $a$, as shown by the arrowheads on the conductors, and will neu-

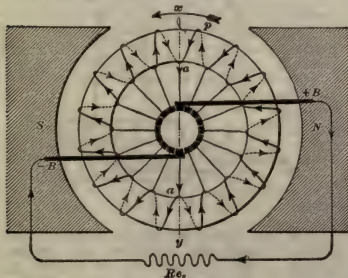
FIG. 3

tralize each other so that no current will flow through the windings of the armature. Suppose, however, that taps are connected at the points $a$ and $a'$, as shown by the dotted lines, and these taps connected to two conducting metal rings $r$ and $r'$, mounted so as to revolve with the armature. By allowing brushes $b$ and $b'$ to press on these rings, connection can be made with an outside circuit $d$, which may consist of a number of lamps or any other device through which it is desired to send a current. By putting in the taps at $a$ and $a'$, the two opposing electromotive forces may be set up a current through the common connections to the rings, and thence through the outside circuit. Current now flows in each half of the armature winding, unites at $a$, flows out by means of ring $r'$ and brush $b'$, thence through the outside circuit $d$ to brush $b$ and ring $r$, from whence it passes to $a'$, and thus completes the circuit. When the ring makes a half revolution from the position in the figure, the current in the outside circuit will flow in the opposite direction. In fact, an arrangement of this kind will deliver a current that will be periodically reversing in the outside circuit; it will be what is known as an *alternating current*.


Instead of simply bringing out two terminals to rings, suppose the winding to be tapped at a fairly large number of points, and connections brought down

FIG. 4

to a number of metal bars insulated from one another, as shown in Fig. 4. When the armature is revolved the brushes will come in contact with successive bars and keep the outside circuit in such relation to the armature winding that the current will always flow through it in the same direction. Moreover, if the number of divisions in the armature is large, the current will fluctuate very little, being nearly as steady as that obtained from a battery. The arrangement made up of insulated bars is called the commutator, because it commutes or changes the relation of the outside circuit to the armature winding so that the current in the outside circuit

always flows in the same direction. All practical machines used for the generation of direct current must be provided with such a commutator. When alternating currents are used it is only necessary to use plain collector rings, as shown in Fig. 3.


**Factors Determining Electromotive Force Generated.**—A dynamo should be looked upon as a machine for maintaining an electric pressure rather than as a machine for generating a current. A pump does not manufacture water—it merely maintains a head or pressure that causes water to flow wherever an outlet is provided for it to flow through. In the same way, a dynamo maintains a pressure, and this pressure will set up a current whenever the circuit is closed, so that the current can flow. The important thing to consider, therefore, is the electromotive force that the dynamo is capable of generating.

The electromotive force generated by an armature depends on the total number of magnetic lines cut through per second by the armature conductors. This means that (1) the faster the armature runs, the higher will be the electromotive force; (2) the greater number of conductors or turns there are on the armature, the higher will be the electromotive force; and (3) the stronger the magnetic field, the higher will be the electromotive force. The electromotive force in terms of these quantities may be written

$$E = \frac{nCN}{100,000,000}$$

in which    $n$ = speed, in revolutions per second;
            $C$ = number of conductors on face of armature;
            $N$ = number of magnetic lines flowing from one pole.

The constant 100,000,000 is necessary to reduce the result to volts. This makes it possible to make calculations relating to any two-pole dynamo, and with slight modification it is applicable to machines with field magnets having a number of poles.

**Field Excitation of Dynamos.**—In the earliest form of dynamo, the magnetic field in which the armature rotated was set up by means of permanent magnets. Permanent magnets are, however, very weak compared with electromagnets, which are excited by means of current flowing around coils of wire wound on a soft-iron core. As soon as the current ceases flowing around the coils of an electromagnet, the magnetism almost wholly disappears, but a small amount, known as the *residual magnetism*, remains. It is to this residual magnetism that the dynamo owes its ability to start up of its own accord and excite its own field magnets. When the armature is first started to revolve, a very feeble electromotive force is generated in it, but the armature is connected to the field coils in such a way that this small electromotive force is able to force a small current through the field coils, and thus set up a larger amount of magnetism in the field. This in turn increases the electromotive force in the armature, and the building-up process goes on rapidly until the dynamo generates its full pressure. There are three methods in use for supplying the field coils with current, and continuous-current dynamos are divided into three classes, according to the method used for exciting their fields. These three classes are: Series-wound dynamos, shunt-wound dynamos, and compound-wound dynamos.

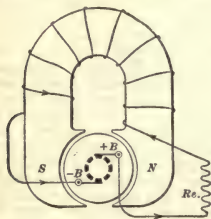


FIG. 5

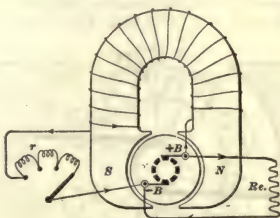

FIG. 6

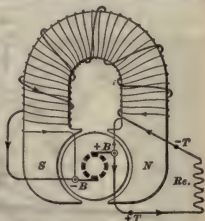
In *series-wound dynamos* the field coils are connected in series with the armature, and all the current that passes through the armature also passes through the field and the outside circuit. This arrangement is shown in Fig. 5, where $N$ and $S$ represent the poles of the magnet, $+B$ and $-B$ the brushes, and $Re$ the outside circuit, which may consist of lamps, motors, or any other device in which it is desired to utilize the current. With an arrangement of this kind, and as long as the speed does not change, the electromotive force will increase as the current increases, because the field will become stronger. This will be true up to the point where the field carries all the

magnetism it is capable of, or, in other words, until it becomes saturated. After this point is reached, the electromotive force will increase very little with increase of current. In most of the work connected with lighting or power transmission, it is desirable to have the voltage remain nearly constant. For this reason, therefore, the series method of excitation has not been very largely used for dynamos. The only style of generator to which it has been applied at all generally is the arc-light dynamo, and these machines are provided with an automatic regulator of some kind to vary the voltage as desired. The series field winding has, however, been largely used in connection with the motors operated on constant-pressure circuits.

*Shunt-wound dynamos* have not been used largely of late years, although they were formerly very common. In this method of excitation, the field is connected as a shunt or by-pass to the armature; that is, the field winding is connected in parallel with the armature. This winding consists of a large number of turns of fine wire, so that its resistance is high and only a small part of the total current flows through it. Fig. 6 shows the connections for this kind of field excitation. An adjustable resistance $r$ is usually inserted in the field circuit, and by cutting this resistance in or out, the field may be weakened or strengthened and the voltage varied accordingly. With this type of machine, the current through the field does not vary greatly from no load to full load, and if the dynamo is well designed, the pressure at the brushes will keep approximately constant. The pressure will, however, always fall off more or less as the amount of current produced increases on account of the drop in the armature, due to its resistance, and also because of the tendency that the current in the armature has of weakening the field. The shunt winding is used quite largely for motors.

The *compound-wound dynamo* is the one most largely used for direct-current power and light distribution, and it is so called because the winding used for exciting the field is a combination of the series and shunt windings. The series winding serves to keep up the field strength while the load is increased, and thus keeps the pressure constant, or even makes it rise with increased load, if so desired. When the series winding is so adjusted that the pressure rises as the load is increased, the machine is said to be *overcompounded*. Fig. 7 shows the connections for such a machine. It will be seen that the shunt winding is connected as before, a field resistance or rheostat, not shown in the figure, being inserted for the purpose of adjusting the voltage. One brush connects directly to one terminal of the machine $+T$, while the other brush connects to one end of the series winding on the field. The other end of the series winding forms the other terminal $-T$, to

FIG. 7

which the outside circuit $Re$ is connected. By this arrangement, the shunt coil supplies a certain amount of initial magnetization that is augmented by the magnetism supplied by the series coils. Care must be taken to see that the current in the series coils circulates around the field in the same direction as that in the shunt coils, otherwise the electromotive force will fall off with an increasing load instead of keeping it up.


## DIRECT-CURRENT MOTORS

*Direct-current motors*, so far as their fundamental construction goes, are almost identical with direct-current dynamos. But as motors are often required to operate under very trying conditions, as in mine haulage or pumping plants or on the ordinary street car, the mechanical construction must be so designed as to enclose the working parts as completely as possible, and thus protect them from dirt and injury. The two kinds of motors most commonly used are the series and shunt varieties; compound-wound motors are only used for a few special kinds of work. Practically all the motors in use are operated from constant-pressure mains; that is, the pressure at the terminals of the motor is practically constant, no matter what load it may be carrying. Only constant-potential motors will be considered here.

**Principles of Operation.**—If the fields of an ordinary constant-potential dynamo are excited and a current supplied to the armature from some outside source, such as another dynamo $D$, Fig. 1, so that the current enters at $+B$, and passing through the winding in the direction indicated by the arrowheads, leaves at brush $-B$, all the conductors under the $S$ pole face, $b$, $c$, $d$, $e$, $f$, and $g$,

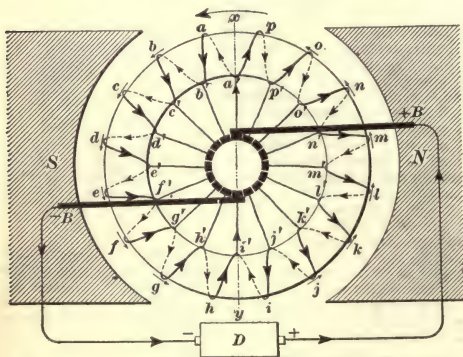
will tend to move *downwards*, and all those under the N pole face, j, k, l, m, n, and o, will tend to move *upwards*, as indicated by the small arrows.

These forces combine to produce a tendency of the armature to rotate about its axis as indicated by the large arrows, which tendency is called the *torque* of the motor.

The amount of this torque—which is usually expressed in pound-feet; that is, a certain number of pounds acting at a radius of a certain number (usually 1) of feet—depends on the strength of the field, the number of conductors, their mean distance from the axis of the armature, and the amperes in each conductor. In any given machine, the second and third conditions are constant, so that the torque depends on the strength of the field and the current.

If the armature is stationary, the electromotive force required to send the current through the winding is only that necessary to overcome the drop, which is due to the resistance of the winding. If the torque exerted by this current is greater than the opposition to motion, so that it causes the armature to revolve, the motion of the conductors through the field generates in them an electromotive force that is opposed to the electromotive force that is sending the current through the armature. This opposing electromotive force or *counter electromotive force* as it is called, then diminishes the effect of the applied electromotive force, so that the current is reduced, thereby reducing the torque. Should the torque still be greater than the opposition to motion, the speed of the armature will continue to increase, increasing the counter electromotive force, and thereby further reducing the current and the corresponding torque until the torque just balances the opposition to the motion, when the speed will remain constant.

At all times, the drop of potential through the armature is equal to the difference between the counter and the applied electromotive forces, and as the product of this drop and the current represents energy wasted, it is desirable



to make it as low as possible. In good motors of about 10 H. P. output, the drop in the armature is seldom more than about 5% of the applied electromotive force, and is less in larger machines. This being the case, it is evident that if the armature is at rest, so that it has no counter electromotive force, and is connected directly to the mains, a very large current will flow through it, which would be liable to damage the armature. On this account an external

Fig. 1

resistance, called a *starting resistance*, is connected in series with the armature when it is to be started. This resistance is made great enough to prevent more than about the normal current from flowing through the armature when it is at rest; as the armature speeds up and develops some counter electromotive force, this resistance is gradually cut out, until the armature is connected directly to the mains, and is running at normal speed.

The energy represented by the product of drop in the armature and the current is wasted; that represented by the product of the current and the rest of the electromotive force, that is, the counter electromotive force, is the energy required to keep the armature in motion.

Aside from the comparatively small amount of current required to furnish the torque necessary for overcoming the frictional losses in the motor itself, which are practically constant, the amount of current taken from the mains is directly proportional to, and varies automatically with, the amount of the external load; for, if this external load is increased, the current that has been

flowing in the armature cannot furnish sufficient torque for this increased load, so that the machine slows down. This decreases the counter electromotive force, which immediately allows more current to flow through the armature, increasing the torque to the proper amount. If the external load is decreased, the current flowing furnishes an excess of torque, which causes the speed to increase, increasing the counter electromotive force, and decreasing the current until it again furnishes only the required amount of torque.

As the counter electromotive force is very nearly equal to the applied, it is only necessary for it to vary a small amount to vary the current within wide limits. For example, if the resistance of a certain armature is 1 ohm, and it is supplied with current at a constant potential of 250 volts, then, when a current of 10 amp. is flowing through it, the drop is $10 \times 1 = 10$ volts, and the counter electromotive force is $250 - 10 = 240$ volts. Now, if the current is reduced to 1 amp., the drop is $1 \times 1 = 1$ volt, and the counter electromotive force is $250 - 1 = 249$ **volts; that is,** the counter electromotive force only varies $\frac{9}{240}$ or 3.75%, while the current varies $\frac{9}{10}$, or 90%.

As stated before, the field magnets of constant-potential motors are usually either shunt-wound or series-wound. If shunt-wound and supplied from a constant-potential circuit, the magnetizing force of the field coils is constant, giving a practically constant field. This being the case, the counter electromotive force is directly proportional to the speed, so that variations of the load make only slight variation in the speed. A shunt-wound motor is then (practically) a constant-speed motor.

With series-wound motors, the strength of the field varies with the current; if the load on such a motor is reduced, the excess of torque makes the armature speed up, but the increasing counter electromotive force produces a decreasing current, thereby decreasing the field strength, and, consequently, the armature must speed up to a much greater extent, in order to increase the counter electromotive force to the right degree, than would be necessary if the field were constant. If the load is increased, the increase in the current so increases the field strength that the speed must decrease considerably, in order to decrease the counter electromotive force by the right amount. The speed of a series-wound motor, then, varies largely with variations in the load.

An advantage of the series motor is that if a torque greater than the normal is required, it can be obtained with less current than with a shunt motor, since the increased current increases the field strength, which remains practically constant in a shunt motor, and the torque is proportional to both these factors.

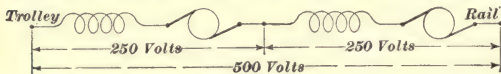
It is not practicable to make the field strength of a shunt motor as great as is possible to get with a series motor, because it would require a very large magnetizing force, and with the shunt winding, this extra magnetizing force would have to be expended all the time, whether the strong field was required or not, which would be very wasteful; in the series-motor, however, this extra magnetizing force is only expended while it is needed.

A disadvantage of the series winding is that if all the load is taken off, the current required to drive the motor is very small, making a weak field, which requires such a high speed to generate the proper counter electromotive force that the armature is liable to be damaged. In other words, the motor will *race*, or *run away*, if the load is all removed. This cannot occur with the shunt motor as long as the field circuit remains unbroken.

On account of the foregoing features, shunt motors are used to drive machinery that requires a nearly constant speed with varying loads, or which would be damaged if the speed should become excessive, such as ordinary machinery in shops and factories, pumps, etc. Series motors are used on street cars, to operate hoists, etc., where, on account of the gearing used, the load cannot be entirely thrown off, except by opening the motor circuit, and the torque required at starting and getting quickly up to speed is much greater than the torque required when the car is running at ordinary speed.

**Speed Regulation of Motors.**—The speed of a motor may be varied by varying the applied electromotive force or the strength of the field. The simplest way to vary the applied electromotive force is to insert a resistance, in series with the armature, similar to the starting resistance. By varying this resistance, the applied electromotive force at the terminals of the motor is also varied, although the electromotive force of the supply circuit remains constant. It is evident that the energy represented by the product of the current and the drop through the resistance is converted into heat, and is thereby wasted; therefore, for great variations in speed, this method is not economical, though

often very convenient. The applied electromotive force may also be varied by varying the electromotive force of the generator supplying the current, but this can only be done where a single generator is supplying a single motor, or several motors, whose speed must all be varied at the same time; so that this method is only used in special cases.



Trolley ⟨⟨⟨⟨⟩⟩ ⟨⟨⟨⟨⟩⟩ Rail

|← 250 Volts →|← 250 Volts →|
|←————— 500 Volts —————→|

FIG. 2

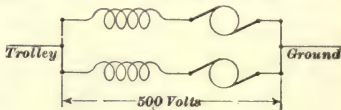
Varying the strength of the field gives a convenient method of varying the speed. If the strength of the field is lessened, the speed will increase, and if the field is strengthened, the speed will decrease. With shunt motors, the field may be weakened by inserting a suitable resistance in the field circuit, as in shunt dynamos; with series motors the same result may be obtained by cutting out some of the turns of the field coils or by placing a suitable resistance in parallel with the field coils. This method of regulation is also of limited range, as it is not economical to maintain the strength of the field much above or below a certain density. The resistance method described, being rather more simple, is generally used. The regulating field resistance must be so constructed as to remain in the circuit all the time the motor is running without getting hot enough to be thereby damaged.

For special cases, such as street-railroad work, various special combinations of the foregoing methods of regulation are used. One of the most common of these is known as the *series-parallel method*, and is the method of regulation generally used at present for operating street cars. This method is equivalent to the method of cutting down the speed by reducing the electromotive force applied to the motor, and is only applicable where at least two motors are used. It is also used, to some extent, in haulage plants. When a low speed is desired, or when the car is to be started up, the motors are thrown in series, as shown in Fig. 2, thus making the voltage across each motor equal to one-half the voltage

Trolley ⟨⟨⟨⟨⟩⟩ Ground
⟨⟨⟨⟨⟩⟩

|←————— 500 Volts —————→|

FIG. 3

between the lines, and cutting down the speed accordingly. When a high speed is desired, the motors are thrown in multiple, as shown in Fig. 3, and each motor runs at full speed because it gets the full line pressure. In practice, starting resistances are used in connection with the foregoing to make the starting smooth, but the two running positions are as shown, the motors being connected in series in the one case, and in parallel in the other.


**Connections for Continuous-Current Motors.**—Fig. 4 shows the manner in which a shunt motor is connected to the terminals $+$ and $-$ of the circuit. The current through the shunt field does not pass through the resistance $R$

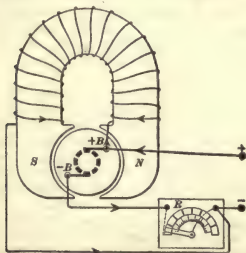


FIG. 4

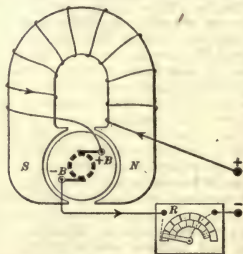

FIG. 5

which is connected in the armature circuit, as to keep the field strength constant, the full difference of potential of the supply circuit should be maintained between the terminals of the field coil. This would not be the case if the rheostat were included in the field circuit, for then the difference of potential

would be only that existing between the brushes $+B$ and $-B$. As on starting the motor this difference of potential is small, only a small current will flow through the field coils, which will generate such a weak field that an excessive current will be required to furnish the necessary torque for starting the motor.

When connected as shown, the field is brought up to its full strength before any appreciable current passes through the armature; so this difficulty does not arise. The current through the armature is gradually increased as the speed increases by gradually cutting out the resistance in the starting box.

As in a series motor the same current flows through both armature and field coils, the starting resistance may be placed in any part of the circuit. The diagram in Fig. 5 illustrates one method of connecting a series motor to the line terminals $+$ and $-$; here the starting or regulating resistance $R$ is placed between the $-$ line terminal and the brush $-B$ of the motor. To reverse the direction of rotation of a motor it is necessary to reverse either the direction of the field or the direction of the current through the armature. It is usual to reverse the direction of the current in the armature, a switch being used to make the necessary changes in the connections.

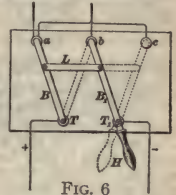

FIG. 6

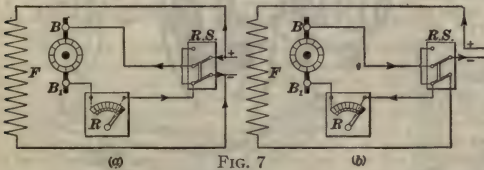
Fig. 6 shows the connections of one form of reversing switch. Two metal bars $B$ and $B_1$ are pivoted at the points $T$ and $T_1$; one is extended and supplied with a handle $H$, and the two bars are joined together by a link $L$ of some insulating material, such as fiber. Three contact pieces $a$, $b$, and $c$ are arranged on the base of the switch so that the free ends of the bars $B$ and $B_1$ may rest either on $a$ and $b$, as shown by the full lines, or on $b$ and $c$, as shown by the dotted lines. The line is connected to the terminals $T$ and $T_1$, and the motor armature between $a$ and $b$, or vice versa, $a$ and $c$ being connected together.

When the switch is in the position shown by the full lines, $T$ is connected to $a$ by the bar $B$, and $T_1$ to $b$ by the bar $B_1$. If the switch is thrown by means of the handle $H$ into the position indicated by the dotted lines, $T$ is connected to $b$ by the bar $B$, and $T_1$ to $a$ by the bar $B_1$ and the connection between $c$ and $a$. The direction of the current through the motor armature, or whatever circuit is connected between $a$ and $b$, is thus reversed.

In order to reverse the current in the armature, the reversing switch must be placed in the armature circuit only. Fig. 7 represents the connection for a reversing-shunt motor $(a)$ and a reversing-series motor $(b)$; $+$ and $-$ are the

(a)     FIG. 7     (b)


line terminals; $R$, the starting resistance; $B$ and $B_1$, the brushes of the motor, and $F$, the field coil of the motor. Some manufacturers combine the starting re-

sistance and reversing switch in one piece of apparatus. When connecting up motors, some form of main switch is used to entirely disconnect the motor from the line when it is not in use.

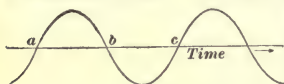
To prevent an excessive current from flowing through the motor circuit from any cause, short strips of an easily melted metal, known as *fuses*, mounted on suitable terminals, known as *fuse boxes*, are placed in the circuit. These fuses are made of such a sectional area that a current greater than the normal heats them to such an extent that they melt, thereby breaking the circuit and preventing damage to the motor from an excessive current. The length of fuse should be proportioned to the voltage of the circuit, a high voltage requiring longer fuses than a low voltage, in order to prevent an arc being maintained across the terminals when the fuse melts.

If desired, measuring instruments (ammeter and voltmeter) may be connected in the motor circuit, so that the condition of the load on the motor may be observed while it is in operation. All these appliances, regulating resistance, reversing switch, fuses, instruments, etc., are placed inside the main switch; that is, the current must pass through the main switch before coming to any of these appliances, so that opening the main switch entirely disconnects them from the circuit, when they may be handled without fear of shocks.

## ALTERNATING-CURRENT DYNAMOS

An *alternating-current dynamo* is one that generates a current that periodically reverses its direction of flow; as when an armature is provided simply with collector rings. This current may be represented by a curve such as that

FIG. 1

shown in Fig. 1. The complete set of values that the current, or electromotive force, passes through repeatedly is known as a *cycle*. For example, the values passed through during the interval of time represented by the distance *ac* will constitute a cycle. The set of values passed through during the interval *ab* is known as an alternation. An alternation is, therefore, half a cycle. The number of cycles passed through per second is known as the *frequency* of the current, or electromotive force.


Alternating-current dynamos are now largely used both for lighting and power transmission, especially when the transmission is over long distances. The reason that the alternating current is specially suitable for long-distance work is that it may be readily transformed from one pressure to another, and in order to keep down the amount of copper in the line, a high line pressure must be used. Pressures much over 500 or 600 volts cannot be readily generated with direct-current machines, owing to the troubles that are likely to arise due to sparking at the commutator. On the other hand, an alternator requires no commutator or even collecting rings, if the armature is made stationary and the field revolving, as is frequently done. Alternators are now built that generate as high as 11,000 volts directly. If a still higher pressure is required on the line, it can be easily obtained by the use of transformers.

Alternating-current dynamos, like direct-current machines, consist of two main parts, the field and armature. Either of these parts may be the revolving member, and in many modern machines the armature, or the part in which the current is induced, is the revolving member. Fig. 2 shows a typical alternator of the belt-driven type, having a revolving armature. It is not unlike a direct-current machine as regards its general appearance. The number of poles is usually large, in order to secure the required frequency without running the machine at a high rate of speed. The frequencies met with in practice vary all the way from 25 to 150. The higher frequencies are, however, passing out of use, and at present a frequency of 60 is very common. This frequency is well adapted both for power and lighting purposes. When machines are used almost entirely for lighting work, frequencies of 125 or higher

FIG. 2

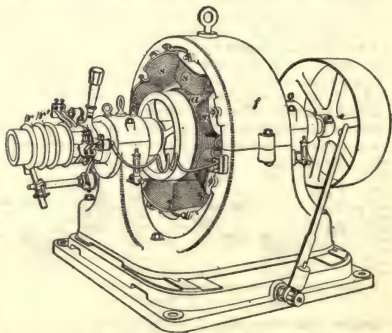
may be used. The frequency of any machine may be readily determined when the number of poles and the speed is known, as follows:

$$\text{Frequency} = \frac{\text{number of poles}}{2} \times \frac{\text{rev. per min.}}{60}$$

For example, if an eight-pole alternator runs at a speed of 900 rev. per min., the frequency will be

$$f = \tfrac{8}{2} \times \tfrac{900}{60} = 60 \text{ cycles per sec.}$$

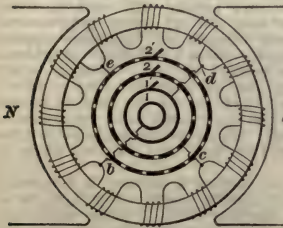
Alternators may be divided into single-phase alternators and multiphase alternators.

*Single-phase alternators* are so called because they generate a single alternating current (as represented by the curve shown in Fig. 1). The armature is provided with a single winding and the two terminals are brought out to collector rings. Single-phase machines have been largely used for lighting work, but they are gradually being replaced by multiphase machines, because


the single-phase machines are not well suited for the operation of alternating-current motors.

*Multiphase alternators* are so called because they deliver two or more alternating currents that differ in phase; that is, when one current is, say, at its maximum value, the other currents are at some other value. This is accomplished by providing the armature with two or more distinct windings which are displaced relatively to each other on the armature. One set of windings, therefore, comes under the poles at a later instant than the winding ahead of it, and the current in this winding comes to its maximum value at a later instant than the current in the first winding. In practice, the two types of multiphase alternators most commonly used are two-phase alternators, and three-phase alternators.

*Two-phase alternators* deliver two alternating currents that differ in phase by one-quarter of a complete cycle; that is, when the current in one circuit is at its maximum value, the current in the other circuit is passing through its zero value. By tapping four equidistant points of a regular ring armature, as shown in Fig. 3, and connecting these points to four collector rings, a simple two-pole two-phase alternator is obtained. One circuit connects to rings *1* and *1'*, the other circuit connects to rings *2* and *2'*. When the part of the winding connected to one pair of rings is in its position of maximum action, the electromotive force in the other coils is zero, thus giving two currents in the



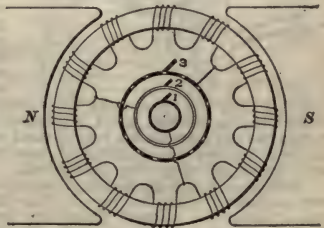


FIG. 3    FIG. 4

two different circuits that differ in phase by one-quarter of a cycle or one-half an alternation.

*Three-phase alternators* deliver three currents that differ in phase by one-third of a complete cycle; that is, when one current is flowing in one direction in one circuit, the currents in the other two circuits are one-half as great, and are flowing in the opposite direction. By tapping three equidistant points of a ring winding, as shown in Fig. 4, a simple three-phase two-pole alternator is obtained. Three mains lead from the collecting rings.

In order to have three distinct circuits, it would ordinarily be necessary to have six collecting rings and six circuits; but this is not necessary in a three-phase machine if the load is balanced in the three different circuits, because one wire can be made to act alternately for the return of the other two.

**Uses of Multiphase Alternators.**—Multiphase alternators are extensively used because alternating-current motors can be readily operated from two-phase and three-phase circuits. By using multiphase machines, motors can be operated that will start from rest under load, whereas with single-phase machines most motors have to be brought up to speed from some outside source of power before they can be made to run. For this reason, such machines are used for the operation of modern power-transmission plants. As far as the general appearance of three-phase machines goes, they are similar to ordinary single-phase alternators, the only difference being in the armature winding and the larger number of collector rings. The multiphase alternator is also adapted for the operation of lights, so that by using these machines both lights and motors may be operated from the same plant. They are well adapted for power-transmission purposes in mines, especially for the operation of pumping and hoisting machinery, because the motors operated by them are very simple in construction and therefore not liable to get out of order.

## ALTERNATING-CURRENT MOTORS

Alternating-current motors may be divided into synchronous motors and induction motors.

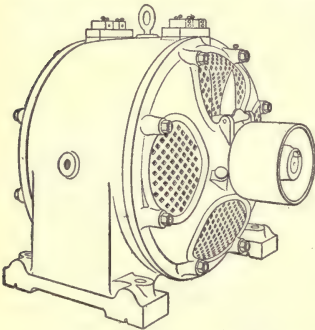
*Synchronous motors* are almost identical, so far as construction goes, with the corresponding alternator. For example, a two-phase synchronous motor

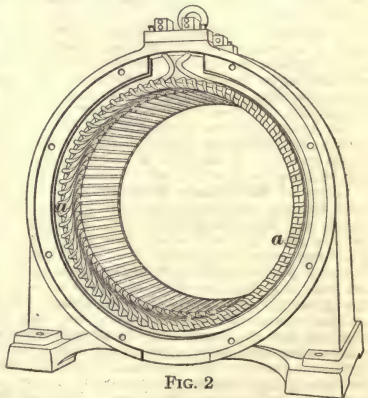
Fig. 1

will be constructed in the same way as a two-phase alternator. They are called synchronous motors because they always run in synchronism, or in step, with the alternator driving them. This means that the motor runs at the same frequency as the alternator, and if the motor had the same number of poles as the alternator, it would run at the same speed, no matter what load it might be carrying. This type of motor has many good points, and is especially well suited to cases where the amounts of power to be transmitted are comparatively large and where the motor does not have to be started and stopped frequently. Multiphase synchronous motors will start up from rest and will run up to synchronous speed without aid from any outside source. Most multiphase synchronous motors will not, however, start with a strong starting torque or effort, and will not, therefore, start up underload, and cannot be used in places where a strong starting effort is required. For this reason most synchronous motors are not suitable for intermittent work. Some special multiphase synchronous motors are so designed, however, that they may be used where a fairly strong starting effort is required.

*Induction motors* are so called because the current is induced in the armature instead of being led into it from some outside source. Fig. 1 shows a typical induction motor. There are two essential parts in these machines, viz., the *field*, into which multiphase currents are led from the line, and the armature, in which currents are induced by the magnetism set up by the field. Either of these parts may be the stationary or revolving member, but in most cases the field, or part that is connected to the line, is stationary. The stationary part of an alternating-current motor is called the *stator* and the rotating part, the *rotor*. Fig. 2 shows the construction of the stationary member or field. This consists of a number of iron laminations, built up to form a core and provided with slots around the inner periphery. Form-wound coils constituting the field winding are placed in these slots and connected to the mains. This winding is arranged in the same way as the armature winding of a multiphase alternator. When alternating currents differing in phase are sent through the winding, magnetic poles are formed at equidistant points around the periphery of the field, and the constant changing of the currents causes these poles to

Fig. 2

shift around the ring, thus setting up what is known as a revolving magnetic field. The armature, Fig. 3, consists of a laminated iron core provided with a number of slots, in each of which is placed a heavy copper




bar *b*. The ends of these bars are all connected together by two heavy short-circuiting rings *r* running around each end of the armature. The bars and end rings thus form a number of closed circuits. When such an armature is placed in the revolving field, the magnetism will cut across the armature conductors, inducing electromotive forces in them, and as the conductors are joined up into closed circuits, currents will flow in them. These currents will react on the field and the armature will be forced to revolve. Such an armature will not run exactly in synchronism, because if it did, it would revolve just as fast as the magnetic field, and there would be no cutting of lines of force. The speed drops slightly from no load to full load, but if the motor is well designed, this falling off in speed is slight.

The name *squirrel cage* is applied to a rotor of the type shown in Fig. 3. Another type of rotor used in induction motors is provided with a coil winding with ends brought out to three collector rings mounted on the shaft. By means of stationary brushes resting on these rings, the resistance in the circuit of such a rotor can be varied. Motors having such rotors are called *wound-rotor* motors, or *slip-ring* motors. Induction motors possess many advantages for mine work. Squirrel-cage motors having no sliding contacts operate with absolutely no sparking—a desirable feature for mine work. Such motors are also very simple in construction, and are therefore not liable to get out of order. They have the additional advantage over the synchronous motor in that they exert a strong starting effort, and, in fact, behave in most respects like any good shunt-wound direct-current motor. They are used quite successfully for all kinds of stationary work, such as pumping, hoisting, etc., but are not adapted for haulage purposes. Wound-rotor (slip-ring) motors are used where especially strong starting effort or variable speed is required.

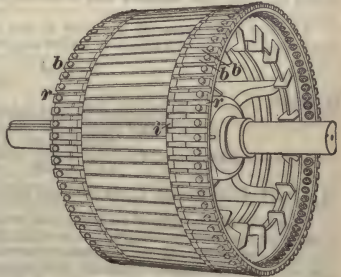


FIG. 3

At no load the speed of an induction motor is practically the quotient obtained by dividing the number of alternations of the current by the number of magnetic poles for which the motor field winding is connected. Thus with a 60-cycle current, or 7,200 alternations, a two-pole motor runs at 3,600 rev. per min., a four-pole motor at 1,800 rev., a six-pole motor at 1,200 rev., an eight-pole motor at 900 rev., a ten-pole motor at 720 rev., a twelve-pole motor at 600 rev., and a fourteen-pole motor at 514 rev. With a 25-cycle current, or 3,000 alternations, the corresponding speeds are 1,500, 750, 500, 375, 300, 250, and 214 rev. per min.

The full-load speed is less than the no-load, or synchronous, speed, and the decrease from no-load to full-load speed is called the *slip*. The slip depends on the resistance of the rotor circuit and on the load, and, the higher the slip with a given load, the lower the efficiency of the motor. In commercial motors, slip ranges in value from 2 to 10% of the no-load speed, depending on the size of the motor, large motors having low slip.

**Selection of Induction Motors for Mine Use.**—Induction motors are made for operating on single-phase, two-phase, and three-phase circuits. Single-phase motors can be used advantageously in small capacities up to, say, 10 H. P., for many purposes. They start with fairly strong effort and operate with efficiency and power factor approximately the same as two-phase and three-phase motors. They require but two line wires and one transformer to increase or decrease the voltage.

In cost and reliability of operation there is little choice between two-phase and three-phase motors, but because the latter require but three line wires as opposed to the four required by the former the resulting saving in copper has led to the more extensive use of the three-phase type. It should be noted, however, that two-phase systems require but two transformers where the voltage has to be changed as against three transformers for the three-phase system.

By the use of static transformers the voltage for induction motors can be made independent of the line voltage. For long-distance transmission lines

the generator voltage is usually *stepped-up* for transmission through the line, and the line voltage *stepped-down* for use in the motors at the end of the line. Large motors can be advantageously operated directly on the line if the voltage does not exceed 6,600, but great care must be taken to keep them dry. High-voltage motors cannot be used successfully in damp places; and low-voltage motors for use in such places should have waterproof insulation on the windings.

The choice of frequency generally lies between the two prevailing standards of 25 cycles and 60 cycles per sec. For railroad work the 25-cycle transmission system is preferred because a better regulation is obtainable and the rotary (synchronous) converters used in connection therewith cost less. For general lighting purposes, both arc and incandescent lamps operate better on 60-cycle circuits. When the voltage does not exceed 110, incandescent lamps are used without flickering on 25-cycle circuits; but when the voltage is high, frequency-changers should be employed to raise the frequency of that portion of the current used for lighting from 25 to 60 cycles. For the operation of stationary motors about mines, the 60-cycle system is generally preferred because the transformers are less costly, because the choice of motor speeds is much greater, and because this frequency is as well adapted to lighting as to power purposes.

The *full-load torque* of a motor is the turning effort it must develop when revolving at its rated speed in order to produce its rated horsepower; that is,

$$\text{H. P.} = \frac{2\pi T \times RPM}{33,000},$$

in which
$\pi = 3.1416$;
$T =$ torque, in foot-pounds;
$RPM =$ the number of revolutions per minute.

By transformation, $T = \dfrac{33,000\,HP}{2\pi \times RPM} = \dfrac{5,250\,HP}{RPM}$. Thus, the full-load torque

of a 10-H. P. motor at 1,700 rev. per min. is $\dfrac{5,250 \times 10}{1,700} = 30.9$ lb.-ft.

The starting torque of an induction motor is that developed at starting from a state of rest and is commonly considerably greater than the full-load torque. The pull-out torque is the maximum turning effort the motor can exert without stopping and is usually from 1.5 to 3 times the full-load torque. An induction motor cannot operate at more than full-load torque, except for short periods, without overheating.

Squirrel-cage induction motors have no wearing parts except the bearings, and these can be made dust-proof, so that these motors rarely need to be enclosed unless they are to be used in extremely dusty places. A free circulation of air through the interior of the motor is necessary to keep it cool. Ordinarily, the necessary circulation is secured by arranging the casing as shown in Fig. 1, where the openings are covered with gratings to prevent objects falling into and injuring the motor. Where the air is only moderately dusty, a supply of clean air may be drawn through a special pipe from outside the motor room and, after circulating through the motor, is discharged through another pipe. For use in very dusty or damp places, the openings in the casing (shown covered by gratings in Fig. 1) are closed with tight-fitting plates; these should be fitted with gaskets to keep out dampness. It must be remembered that this enclosing reduces the capacity of the motor for continuous operation owing to the heating through lack of interior ventilation; in fact, an enclosed motor can operate at full rating only intermittently.

Squirrel-cage motors are generally preferred to wound-rotor motors for driving machinery, such as mine fans, where the speed is constant. By providing a motor of this type with a high resistance rotor, its starting and pull-out torque with a given input of current can be made high, although its efficiency, when running under load, is correspondingly low. For intermittent service where a high torque is necessary for starting or while in operation, squirrel-cage motors with high-resistance rotors are sometimes desirable, as in driving elevators, conveyers, etc.

Wound-rotor motors are preferred for driving machinery such as hoisting engines, which must be frequently started and stopped with a high torque and where ability to change the speed is important. By means of a controller connected with the collector rings, the resistance in the rotor circuit can be varied at will, thus limiting the starting current and giving any desired speed. When driving machines other than hoisting engines where the engineer is constantly on duty, it should be noted that when a motor of this type is operated with external resistance in its rotor circuit, any change in the amount of the

load thrown upon it causes an inverse change in its speed so that, in these cases, also, the presence of an attendant may be necessary to keep the speed adjusted.

Induction motors are usually purchased under guaranteed heating limits and performance characteristics, such as efficiency, power factor, starting and pull-out torque, and, sometimes, slip. The heating limits, or rise in temperature of the windings, etc., of the motor when in operation are at present commonly guaranteed not to exceed 40° C. to 75° C. above the normal temperature; the amount of rise guaranteed depending on the style of motor, whether open, semi-enclosed, or enclosed, and on the nature of the service, whether under continuous or intermittent operation. High efficiency is desirable in a motor that is to be run continuously under a steady load, and the efficiency should be high at this load; the importance of high efficiency in such a motor increases with the cost of electricity. Efficiency is not of importance in a motor that operates intermittently, or where the cost of electricity is very low.

Low power factor indicates that some of the current in the generator and transmission line is useless or idle, in that the energy supplied the motors is less than is indicated by the line current. The actual energy that can be delivered by a generator within its guaranteed heating limits decreases with the power factor. Thus, a generator rated at 1,000 K. W. at 100% power factor would have an output of 900 K. W. at 90% power factor; and similarly, the carrying capacity of transmission lines is reduced in the same way. The power factor of a system depends on the power factors of the motors operating on the lines. A small number of motors operating at low power factors may not affect the general capacity appreciably, but as the number of motors is increased, the importance of operating them at high power factor increases, as the generator and lines may be overloaded with the current.

**Installation and Care of Induction Motors.**—When ordering a motor, the manufacturer should be advised whether it is to be placed on a side wall, suspended in a reversed position overhead, or used on the ordinary horizontal floor, or pedestal, mounting, as the arrangement of the housings, oil cups, etc., will be different in the several cases. The machine should be mounted in the driest, cleanest, and best-ventilated place possible, where it is in plain sight and within easy reach. The foundations should be solid enough to prevent vibration, masonry or concrete construction being preferred. The rails upon which the motor slides in being adjusted to position should be supported upon an absolutely even surface, so that the machine may rest properly upon them. When the motor is belt-connected to the driven machine, the axles of the two should be absolutely parallel, and the centers of the faces of the driving and driven pulleys should be exactly in line, so that the rotor will not be forced from its central position. If the motor is geared to the driven machine, the axles of the two must be parallel, the centers of the faces of the gear-wheels must be in the same line, and the distance between the centers of the gear-wheels must be exactly that demanded by the designs, that the pinion may mesh properly with the gear. If a thin piece of paper is passed through the gears while slowly turning the rotor, it should show by its crushing or marking, an even pressure across the full width of the tooth.

Before starting a motor for the first time, care must be taken that all circuits, connections, etc., are in accordance with the diagram furnished by the manufacturer. With small motors, enclosed type fuses are used in connection with the starter, but with larger motors circuit-breakers are used. Fuses that are not out during starting should have a current capacity at least 2½ times that of the motor. Very small motors require no starting apparatus and may be put in operation by closing the line circuit. In motors of 5 H. P. and upwards, the sudden throwing on of the entire current will cause fluctuations in the line current, which may interfere with the working of other motors on the same circuit and may even damage the motor windings.

To permit the application of low voltage at starting, which may be increased to full voltage after the motor has been brought up to speed, squirrel-cage induction motors are provided with auto or compensating starters. These starters differ in details of design, but in all cases they comprise the essential elements of two or three single-coil transformers for reducing the voltage, and a switch for changing the connections between the line, the transformers, and the motor. The transformers are provided with taps, and by adjusting the tapping-in point the voltage at starting may be varied. In the starting position, the switch connects the transformers to the line and the motor to the transformers. In the running position, the motor is connected directly to the line, no current passing through the transformers. Starters commonly have

but one starting position and open the circuit when passing from the starting to the running position. They are designed so that it is impossible to move from the off to the running position without passing through the starting position, or to introduce the starting connection in passing back from the running to the off position. The handles of most starters are moved clockwise to start and stop the motor, and can be turned in the reversed position only to return from the starting to the off position.

The power should not be thrown on in one rapid operation as such action will cause excessive starting current; rather, the handle should be left at the starting position for a short time, and then moved quickly either to the second starting position (if there is one) or to running.

When setting up a motor, the oil wells should be examined and if dirty should be blown out or cleaned with gasoline if they are badly clogged. After cleaning, they should be filled with a high grade of mineral oil, preferably dynamo oil, which flows easily and is readily carried up by the oil rings. Graphite and similar lubricants are not satisfactory for use in motors as they clog the oil ducts and interfere with the operation of the oil rings. When starting the motor (which may be turned by hand for testing purposes) care must be taken that the rings revolve and carry up the oil. At all times enough oil must be kept in the bearings that the rings may dip well below its surface. Bearings using oil and waste should be packed with a high-grade wool waste, which should fit closely against the shaft. Cotton or the poorer grades of wool waste become soggy and drop away from the shaft. The waste should be thoroughly saturated with oil, preferably by immersing it for 48 hr., and then letting it drip for 10 to 12 hr. Too much free oil will result in an overflow and the possible introduction of oil within the motor. Dirty oil should never be used; it should be replaced at once with clean oil, and to this end an oil filter is an excellent investment. Bearings using grease should be filled with a good quality of grease free from dirt or grit.

The distance between the centers of the driving and driven pulleys should be great enough to allow some sag in the belt. Kent gives the following general rules for belting. With narrow belts and small pulleys, the distance between centers should be 15 ft., with a sag in the loose side of the belt of $1\frac{1}{2}$ to 2 in. With belts of medium width and larger pulleys, the center distance of the pulleys should be 20 to 25 ft., and the sag, $2\frac{1}{2}$ to 4 in. With main belts on very large pulleys, the center distance should be 25 to 30 ft., and the sag from 4 to 5 in. If the distance between pulley centers is too great, the belt will flap unsteadily resulting in unnecessary wear of the belt and bearings; if the distance is too short, the severe tension required to prevent slipping will cause rapid wear and possible overheating of the bearings. The rules given represent good practice for long life of belt and bearings. Shorter distances must sometimes be used, in which cases the belt may be tighter, the belt and pulleys wider, or the pulleys larger and the belt speed greater. Very short belts will work satisfactorily if idler pulleys are used to increase the arc of contact between the belt and pulleys. Belts should not be run at a greater angle with the horizontal than 45° if this is possible, and never vertically. The belt should be just tight enough to avoid slipping or flapping; the slack side should have a gently undulating motion; the joints should be as smooth as possible, and a lapped joint should always trail, never lead over a pulley. A sidewise movement of the belt indicates poor alinement of the pulleys or unequal stretching of the edges of the belt.

When a bearing becomes hot, the cause of the trouble should be looked for at once. Some of the common causes of hot bearings are: Poor grades of oil, grit and dust in the oil well and bearings, stopping of the circulation through foreign particles in the oil grooves, an empty oil well, too tight or too heavy a belt, too much end thrust on the rotor due to poor alining or leveling, a sprung shaft, or worn or cut Babbitt metal in the bearings. The bearings of induction motors should be inspected daily, because the air gap between the rotor and stator being small, any excessive wear on the bearings may cause these parts to rub. Some of the larger sizes of induction motors are provided with adjustable bearings so that the rotor may be shifted to secure a uniform air gap, but in the smaller sizes the effects of wear can be overcome only by renewing the linings.

Dust and grit should not be allowed to accumulate around the windings and bearings. The motor should be regularly and thoroughly wiped and the dust blown from all its parts. The projecting portions of the stator coils of motors running in damp places should receive an occasional coating of waterproof insulating varnish.

The temperature of all induction motors will rise above that of the atmosphere while running under load. As long as the hand can be held continuously on the machine there is no danger, but as soon as the heat can be borne but for a few seconds, and particularly if the odor of burning oil is noticeable, the danger point has been reached. It will seldom be necessary to do more than supply the bearings with an abundance of fresh clean lubricant, care being taken that the oil or grease reaches the bearing surface; sometimes it may be necessary to remove excessive belt tension. If relief is not afforded in this way, a heavy oil should be poured directly on the journal if possible. If necessary, part or all of the load should be removed but the rotor should be kept in motion enough to prevent the bearing from becoming set or *frozen*.

When an induction motor is overloaded beyond its limit, it will stop or *pull-out*. Should a motor stop when it is not overloaded, and an examination of the bearings and air gap shows that the motor and stator are not rubbing, the stoppage may be due to abnormally low voltage in the supply circuit. The torque exerted by induction motors decreases as the square of the voltage; hence, a comparatively small drop in the voltage produces a large decrease in torque and the motor may come to a standstill if it happens to be carrying a heavy load at the time the voltage drops. To secure the best results from an induction motor, full voltage should be maintained and it is better to have the voltage too high than too low provided excessive heating does not result therefrom.

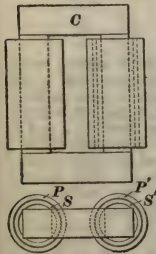
# TRANSFORMERS

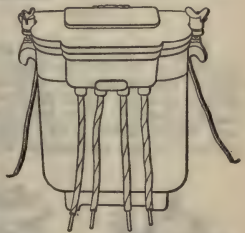
*Transformers* used for raising the voltage are known as *step-up transformers;* those used for lowering the pressure are known as *step-down transformers.*

The transformer consists of a laminated iron core upon which two coils of wire are wound; these coils are entirely distinct, having no connection with each other. One of these coils, called the *primary*, is connected to the mains; the other coil, called the *secondary*, is connected to the circuit to which current is delivered. Fig. 1 shows the arrangement of

FIG. 1

FIG. 2

coils and core for a common type of transformer. The secondary coil is wound in two parts $S$ and $S'$, and the primary coil, also in two parts $P$ and $P'$, is placed over the secondary. $C$ is the core, built up of thin iron plates. Fig. 2 shows a weather-proof cast-iron case for this transformer. When a current is sent through the primary it sets up a magnetism in the core which rapidly alternates with the changes in the current. This changing magnetism




sets up in the secondary an alternating electromotive force, which depends on the number of turns in the secondary coil. If the secondary turns are greater than the primary, the secondary electromotive force will be higher than that of the primary. The relation between the primary electromotive force and secondary electromotive force is given by the following:

$$\text{Secondary E. M. F.} = \text{primary E. M. F.} \times \frac{\text{secondary turns}}{\text{primary turns}}$$

or,

$$\text{secondary E. M. F.} = \frac{\text{primary E. M. F.}}{\dfrac{\text{primary turns}}{\text{secondary turns}}}$$

The ratio $\dfrac{\text{primary turns}}{\text{secondary turns}}$ is known as the ratio of transformation of the transformer. For example, if a transformer had 1,200 primary turns and 60 secondary turns, its ratio of transformation would be 20 to 1, and the secondary voltage would be one-twentieth that of the primary. Transformers are made for a number of different ratios of transformation, the more common ones being 10 to 1 or 20 to 1. Of course, a transformer never gives out quite as much

33

power from the secondary as it takes in from the primary mains, because there is always some loss in the iron core and in the wire making up the coils. The

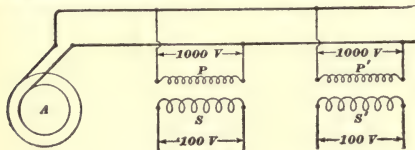


FIG. 3

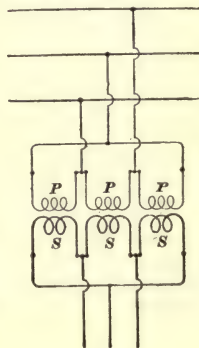

FIG. 4

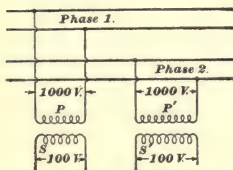
FIG. 5


efficiency of transformers is, however, high, reaching as high as 97% or 98% in the larger sizes. Transformers are connected in parallel across the mains, and if they are well designed, will furnish a very nearly constant secondary pressure at all loads, when furnished with a constant primary pressure. Fig. 3 shows transformers connected on a single-phase circuit, Fig. 4 shows the connection for a two-phase circuit, and Fig. 5 shows one method of connection for a three-phase circuit.

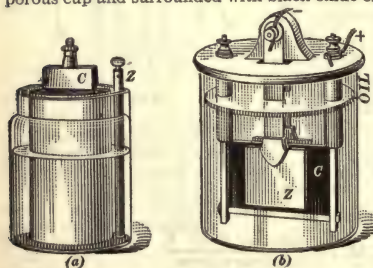
# ELECTRIC SIGNALING

## BATTERIES

*Batteries* are used for various purposes in connection with mining work, principally for the operation of bells and signals. The *Leclanché cell* is one that is widely used for bell and telephone work. It is made in two or three different forms, one of the most common being shown in (a) of the accompanying illustration. The zinc element of this battery is in the form of a rod $Z$, and weighs about 3 oz. The other electrode is a carbon plate placed in a porous cup and surrounded with black oxide of manganese, mixed with crushed coke or carbon. The electrolyte used in the battery is a saturated solution of sal ammoniac. The electromotive force of this cell is about 1.48 volts when the cell is in good condition. In another form of the cell, known as the *Gonda* type, black oxide of manganese is pressed into the form of bricks and clamped against each side of a carbon plate by means of rubber bands. The Leclanché type of cell will do good work if it is only used intermittently in circuits where the insulation is good and where there is no leakage causing the cell to give out current continuously. If current is taken from it for any length of time, it soon runs down, but will recuperate if allowed to stand.



(a)    (b)

Dry cells are essentially the same as a Leclanché liquid cell, but the electrolyte is limited to the amount that can be retained in some absorbent material, such as paper, that is placed inside a zinc can which forms one electrode. The other electrode is a carbon rod in the center. The space between is filled with crushed coke and peroxide of manganese and the whole interior is saturated

## ELEMENTS OF PRIMARY BATTERIES

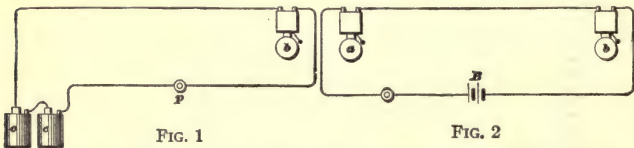
| Name | Anode | Electrolyte | Cathode | Depolarizer | E.M.F. | Remarks |
|---|---|---|---|---|---|---|
| Fuller | Amalgamated zinc | Sulphuric acid (very dilute) or water, in porous cup | Carbon | Sodium bichromate, 6 oz; sulphuric acid, 17 oz.; soft water, 56 oz. | 2.14 | Anode in porous cup with a little mercury. |
| Partz | Zinc | Sodium chloride or magnesium sulphate | Carbon | Same as in the Fuller battery | 1.9 to 2 | Gravity cell; resistance with sodium chloride, .5 ohm; with magnesium sulphate, 1 ohm. For closed-circuit work only; resistance 3 ohms. |
| Gravity Daniell | Zinc | Zinc sulphate, specific gravity 1.10 | Copper | Copper sulphate with copper sulphate crystals | 1.07 | For closed-circuit work only; resistance 3 ohms. |
| Leclanché | Zinc | Ammonium chloride saturated | Carbon | Peroxide of manganese | 1.48 | Carbon and depolarizer in porous cup; resistance, 4 ohms; for intermittent service. |
| Edison | Zinc | Caustic potash | Molded plates of cupric oxide held in copper frames | | .7 | Surface of electrolyte covered with layer of oil; resistance about .7 ohm, depending on size of cell. |
| Gordon | Zinc | Caustic soda | Flaky copper oxide in perforated copper cylinder | | .7 | For open- or closed-circuit working |
| Dry | Zinc | Ammonium chloride | Carbon | Peroxide of manganese | 1.4 | For intermittent service; internal resistance, .1 to .8 ohm. |

with the solution and the top sealed to prevent its evaporation. Dry cells are extensively used in place of wet Leclanché cells because they are as good and so much cheaper that it is economical to throw them away when exhausted and buy new ones instead of spending the time and money required to replenish the wet Leclanché cells. The internal resistance of cells not over 1 yr. old nor entirely exhausted varies from .1 to .8 ohm and the electromotive force from 1.3 to 1.5 volts.

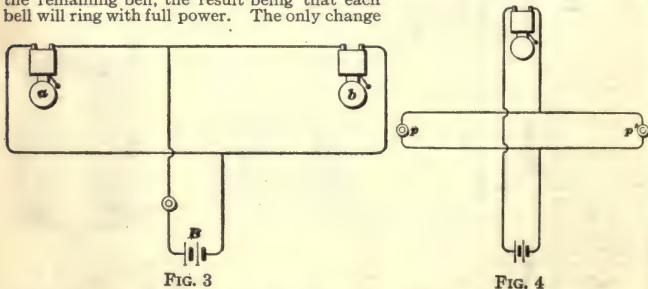
In cases where the insulation is apt to be poor, as it often is in mines, it is best to use a battery that will stand a continuous delivery of current and that will at the same time operate all right on intermittent work or on work where the circuit is open most of the time. For work of this kind, cells of the *Edison* or *Gordon* type are excellent. View (*b*) shows the Edison cell. The elements consist of two zinc plates *Z* hung on each side of a plate of compressed cupric oxide *C*. The electrolyte is a saturated solution of caustic potash, which is kept covered with a layer of heavy paraffin oil, to prevent the action of the air on the solution. The voltage of the cell is only .7 volt, but its internal resistance is very low and its current capacity correspondingly large. The electrolyte used in the Gordon cell is also caustic-potash solution, and the two cells are much the same, so far as their general characteristics are concerned. The preceding table gives data relating to a number of different types of cell.

## BELL WIRING

The simple bell circuit is shown in Fig. 1, where *p* is the push button, *b* the bell, and *c* the cells of the battery connected up in series. When two or more

FIG. 1                                    FIG. 2


bells are to be rung from one push button, they may be connected in series, as shown in Fig. 2, or arranged in parallel across the battery wires, as at *a* and *b*, Fig. 3. The battery *B* is indicated in each diagram by short parallel lines, this being the conventional method. In the parallel arrangement, the bells are independent of each other, and the failure of one to ring will not affect the others; but in the series grouping, all but one bell must be changed to a single-stroke action, so that each impulse of current will produce only one movement of the hammer. The current is then interrupted by the vibrator in the remaining bell, the result being that each bell will ring with full power. The only change

FIG. 3                                    FIG. 4


necessary to produce this effect is to cut out the circuit-breaker on all but one bell by connecting the ends of the magnet wires directly to the bell terminals.

When it is desired to ring a bell from one of two places some distance apart, the wires may be run as shown in Fig. 4. The pushes *p* and *p'* are located at the required points, and the battery and bell are put in series with each other.

A single wire may be used to ring signal bells at each end of a line, the connections being given in Fig. 5. Two batteries are required, $B$ and $B'$, and

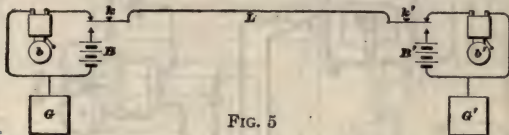


FIG. 5

a key and bell at each station. The keys $k$ and $k'$ are of the double-contact type, making connections normally between bell $b$ or $b'$ and line wire $L$. When one key $k$ is depressed, a current from one battery $B$ flows along the wire through the upper contact of the other key $k'$ to a bell $b'$ and back through the ground plates $G'$ and $G$.

When a bell is intended for use as an alarm apparatus, a constant-ringing attachment may be introduced, which closes the bell circuit through an extra

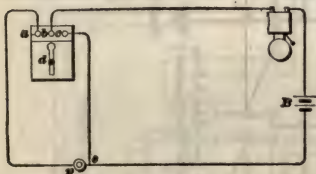

FIG. 6

wire as soon as the trip at a door or window is disturbed. In the diagram, Fig. 6, the main circuit, when the push $p$ is depressed, is through the automatic drop $d$ by way of the terminals $a$ and $b$ to the bell and battery. This current releases a pivoted arm which, on falling, completes the circuit between $b$ and $c$, establishing a new path for the current by way of $e$, independent of the push $p$. The bell will then ring until the drop $d$ is restored by some one or the battery becomes exhausted. For operating electric bells, any good type of open-circuit battery may be used; dry and Leclanché cells are largely used for this purpose.

**Annunciator System.**—The wiring diagram for a single annunciator system is shown in Fig. 7. The pushes *1, 2, 3,* etc., are located in various places, one side being connected to the battery wire $b$, and the other to the leading wire $l$ in communication with the annunciator drop corresponding to that place. A battery $B$ of two or three Leclanché cells is placed in any convenient location. The size of wire used throughout may be No. 18 annunciator wire.

Telephones are also used for signaling and communicating purposes. The mine telephone system performs two functions: It expedites the work, thereby lowering the cost of production, and it enhances the safety of the mine workers and mine property. Its value was realized first by some of the leading mining companies and several states have enacted mine laws requiring its use. The principles involved in a mine telephone system are identical with ordinary telephone practice, with such changes in details as are necessary to meet conditions existing in mines.

The telephone case in mine work must be damp-proof and dust-proof, and wiring must be of such a nature as to resist both dampness and the corroding influence of drops of acidulated mine water. It must also be

FIG. 7

suspended so as to be protected from injury due to falls of roof, cars, or the carelessness of employes.

It has been found that a first-class, long-distance, bridging telephone is the best type to use; *bridging telephones* are so called because they are bridged

or connected in parallel across the line, and are not connected in series. If one telephone should get out of order, the others are not likely to be disabled. Figs. 8 and 9 show the system of wiring and installation used by the Stromberg-Carlson Telephone Manufacturing Company. It will be noted that there is a metallic circuit for the telephones separate and distinct from that used for either lighting or emergency bells.

Fig. 10 shows the combined telephone and emergency (alarm) system of bells employed by the Western Electric Company, in which three wires are used. As in the case shown in Fig. 8, a separate generator is employed to ring the alarm bells. One of these is installed at some central point on the surface where some one is always on duty to receive telephone calls from points inside the mine and, if necessary, to sound the alarm bells. Other generators may be installed at other points, say, at the foot of the shaft or at the inside parting, from which it may be desirable to be able to send warning signals in event of accident.

Fig. 11 shows a complete bell annunciator and telephone outfit as installed in one of the anthracite mines of the D., L. & W. R. R. Co. Bridging instruments are used and each bell in the shaft is provided with a return-call button. This bell wiring should be put up in a substantial manner, and it is best, if possible, to run all the wires down the shaft in the shape of a lead-covered cable. Another shaft-signaling apparatus is shown in Fig. 12, as used at the West Vulcan mines, Mich. Fig. 13 shows a form of waterproof push button used at the same mine. Fig. 14 shows the arrangement of flash signals as used in Montana. This consists of a switch cut into a lighting circuit at each level of the mines. By pulling out the handle bar of the switch, all the lights on this circuit can be flashed at once, and by a properly arranged code of flash signals, the system can be used for communicating between the surface to any part of the mine, and between different portions of the mine.

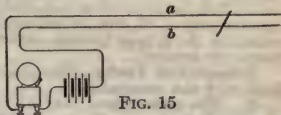
FIG. 14

A system of signaling by which signals can be sent to the engine room from any point along the haulage road is shown in Fig. 15. The bare conductors $a$ and $b$ leading from the battery are supported on insulators parallel to each other along the roadside, and about 6 in. apart. A short iron rod, placed across the wires $a$, signals to the engineer, or by simply bringing the two wires together a signal may be sent. When the engineer hauls from different roads, the signaling system

FIG. 15

should be supplemented with indicators, so that when the bell rings the indicator will show from which point the signal came, and in case several signals were given at the same time, the engineer should not heed any until the indicator shows that a complete signal came from one place.


A system of signaling for showing whether or not a section of track is occupied by another motor is shown in Fig. 16. White lights indicate a clear

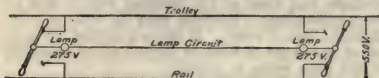


FIG. 16

track and darkness an occupied section. A single-center hinge, double-handle switch at each signal station is used and a touch of the handle throws the switch in the desired direction. The switches are placed in the roof, $4\frac{1}{2}$ ft.

above the rails within easy reach of the motorman. Each switch is provided with a spring (not shown in the figure) which, drawing across the center hinge when the handles are in their central position, insures a perfect contact when the switch is inclined toward either the trolley or rail-terminal plug.

# DYNAMO AND MOTOR TROUBLES

## SPARKING AT BRUSHES

Faults in dynamos and motors may be classed as follows: Sparking at the brushes; heating of armature, field coils, and bearings; noise; too high or too low speed. Besides, a motor may stop, fail to start, or may run backwards or against the brushes and a dynamo may fail to generate electricity.

**Brush Faults.**—Sparking at brushes may be due to some fault with the brushes.

1. The brushes may not have been set diametrically opposite one another because they were not set properly while at rest by counting the bars, by measurement, or by the use of reference marks on the commutator. Brushes can be set properly, if necessary, in an emergency while the machine is running by bringing the brushes on one side to the least sparking point by moving the rocker-arm, and then adjusting the brushes on the other side to the least sparking point by moving in or out the brush holder and clamping in new positions.

2. The brushes may not have been set at a neutral point. In this case, move the rocker-arm slowly back and forth until the sparking is stopped or reduced to a minimum.

3. The brushes may not have been properly trimmed. If sparking begins from this cause and the dynamo cannot be shut down, bend back and cut off the loose and ragged wires; retrim as soon as possible after the machine is shut down. If there are two or more brushes in each set they may be changed one at a time on a low-voltage machine while it is running. If there is a singing or hissing at the brushes apply a little mineral oil or better yet vaseline, or hold a piece of stearic-acid candle on the commutator a moment and then wipe off, leaving just a faint trace of oil or grease. To eliminate noise, it may be necessary to lengthen or shorten the brushes in the holders until a firm but gentle pressure is maintained free from vibration. Use only a cloth, never waste, to wipe off commutator.
